Irregular triangle, read by rows, where row n lists the coefficients of nonpositive powers of x in the doubly infinite series Sum_{k=-oo..oo} x^k * (1 - x^k)^(n+k) for n >= 1.

Conjectural formulas for the terms of this triangle: (2) Sum_{k=0..floor((n+1)/2)^2} T(n,k) = 0 for n >= 1 (conjecture). (3) Sum_{k=0..floor((n+1)/2)^2} k * T(n,k) = 1 for n >= 1 (conjecture). (4) Sum_{k=0..floor((n+1)/2)^2} k^2 * T(n,k) = -(2*n-5) for n >= 2 (conjecture). (5) Sum_{k=0..floor((n+1)/2)^2} -(-1)^k * T(n,k) = 2*round(2^n/3) = 2*A001045(n) for n >= 1 (conjecture), where A001045 is the Jacobsthal numbers (g.f. x/((1+x)*(1-2*x))). (6) Sum_{k=0..floor((n+1)/2)^2} -(-1)^k

* k * T(n,k), n >= 1, forms a sequence with g.f. x*(1-x+8*x^2)/((1+x)^2*(1-2*x)^2) (conjecture), and begins [1, 1, 13, 25, 81, 181, 453, 1025, ...].

V3-017488 | OEIS-A392664

Triangle read by rows: T(n,k) (1 <= k <= n) given by T(n,1) = T(n,n) = 1, otherwise T(n,k) = (m*n-m*k+1)*T(n-1,k-1) + (m*k-m+1)*T(n-1,k), where m = -3.

Conjecture: T(n,k) >= 0 for all even n and all 1 <= k <= n. Verified for even n <= 400. Since all entries are nonneg for even n, the roots of R_n(y) lie in the annulus determined by consecutive coefficient ratios (Enestrom-Kakeya theorem).

V3-017520 | OEIS-A393217

Perfect powers m^k, with m, k > 1, such that no digit of m^k is present in k^m.

Conjecture: For n > 20, a(n) is of the form 10^k or m^10. The sequence A062518 gives the conjectural largest exponent k such that n^k does not contain all digits from 0 to 9. Then, given m > 1, with the exception of m = 10, for large exponents it is very likely that both m^k and k^m are pandigital numbers, and therefore share digits. From this observation, and considering that 10^k contains only the digits 0 and 1, if one wants m^k and k^m to have no digits in common, this is more likely to occur when m = 10. For example, the numbers 10^5, 10^7, 10^14, 10^118, 10^976 and 10^71637 are terms of this sequence.

V3-017526 | OEIS-A393434

a(0) = 0; thereafter a(n) is the least integer (in absolute value) not yet in the sequence such that the absolute difference between a(n-1) and a(n) is a factorial number k!, k >= 1; in case of a tie, preference is given to the positive value.

It is conjectured that every integer appears in this sequence. (It appears that the proof in A379719 can be modified to apply here. The start is somewhat irregular, but beginning at n = 25, the positive terms appear in blocks of consecutive numbers, where block B(k), k >= 4, has length k*k!/2, starts at n = k!/2 + 1 and ends at n = (k+1)!/2. The structure of

the negative blocks is less clear.)

a(n) is the smallest index k such that the subsequence b(k), b(k+1),..., b(k+n-1) is a palindrome of length n, where b(k) = A206400(k).

The aim of this sequence is to study the local symmetries of the differences between prime numbers of the form m^2+1. To do this, we identify palindromes in subsequences of A206400. This research falls within the framework of the fourth problem posed by the mathematician Edmund Landau at the 1912 International Congress of Mathematicians (Landau, 1912). This problem, still unsolved to this day, conjectures the existence of infinitely many prime numbers of the form k^2+1.

V3-017564 | OEIS-A394258

Largest prime less than the n-th prime-complete number.

A double (two prime-complete numbers in one prime gap) occurs only for the shared previous-primes 31, 89, 479, and 4603; no further double exists below 10^12, and a heuristic based on the density of prime-complete numbers suggests this list of doubles is complete and that no triple occurs. That is, the counting function for prime-complete numbers, A377028(n), grows sub-polynomially (empirically exp(O(sqrt(log n)))), so prime-complete numbers thin out faster than any polynomial while prime gaps grow only logarithmically. The expected number of further doubles beyond x is therefore a convergent sum, supporting the conjecture that the complete list is 31, 89, 479, and 4603.

V3-017565 | OEIS-A394263

Positive integers k for which the Euclidean distance between the vector of proportions of the first k decimal digits of Pi and the uniform distribution (1/10, ..., 1/10) sets a new minimum.

Conjecture: The digit proportions of an initial segment of the decimal expansion of Pi can get arbitrarily close to, but not equal to, the uniform distribution. This implies that there are infinitely many terms in this sequence and in the related sequences A394264 and A394265.

V3-017584 | OEIS-A394532

Numbers k such that every abelian group of order k appears as a group of units of the ring Z/mZ for at least one m.

For general totient numbers t, the map f_t is injective for t = 2^s, s >= 33, assuming five Fermat primes. See the Englezou link for a proof. This raises the interesting question whether f_r is injective for r <> 2^n. A negative claim would constitute a generalization of Carmichael's totient conjecture. The above generalization of Carmichael's conjecture is false. f_k is injective for many primes p such that k = p * 2^r: for example, it is injective for k = 11 * 2^203, k = 17 * 2^111, and k = 19 * 2^89. For a method of determining that f_k is noninjective for k = p * 2^r over all r >= 1, see the comment in A398282. - _Miles Englezou_, Jul 25 2026

V3-017609 | OEIS-A394906

Representation of n in a positional system with the k-th prime as the k-th place value, choosing the representation that maximizes the decimal value.

Conjecture: For every d > 0 there exists n such that a(n) has exactly d nonzero digits. Conjecture: a(n) is defined for all n >= 2. Conjecture: The two least significant (rightmost) digits are in {0,1,2}; all other digits are in {0,1}. Proof of the first conjecture: If a(n) has m nonzero digits and p > n is a prime such that nextprime(p) > p + n, then a(p + n) has m+1 nonzero digits: a leading digit 1, followed by primepi(p) - length(a(n)) - 1 zeros, followed by the digits of a(n). Since prime gaps are known to become arbitrarily large, such a prime p always exists. - _M. F. Hasler_, Apr 08 2026

关键词命中原段；序列定义见题名及原页面 | 原始来源 | CC BY-SA 4.0

V3-017619 | OEIS-A395126

a(n) = fourth coordinate d of the n-th P-position (a,b,c,d) of 4 X n Chomp in lexicographic order, where a>=b>=c>=d>=0 gives row lengths.

A position (a,b,c,d) with a>=b>=c>=d>=0 is a P-position of 4 X n Chomp if the player to move loses under optimal play. This sequence lists the d-values of all such positions sorted lexicographically by (a,b,c). The first 10 positions in order are: (1,0,0,0), (2,1,0,0), (2,2,1,0), (2,2,2,1), (3,1,1,0), (3,2,0,0), (3,3,1,1), (4,1,1,1), (4,2,2,0), (4,3,0,0). Computed for all n<=500, yielding 4316097 P-positions with zero violations of the Unique Extension conjecture: for any triple (a,b,c), at most one value of d completes a P-position. This is an empirical observation, not a proof.

a(n) is the smallest number where the largest density of numbers with the same signature as A025487(n) among the first a(n) positive integers occurs.

Let Q(s, n) be the number of numbers <= n with prime signature s. Then a(n) is the (conjectured) smallest value k that maximizes the ratio Q(s, k)/k.

V3-017643 | OEIS-A395522

Square table read by antidiagonals downwards: T(n,k) is the period of {F^(n)(x) mod k} for n >= 1, k >= 1, where F^(n) means the n-th iteration of the Fibonacci sequence (A000045).

Conjecture: each column is eventually constant. See the Math Stack Exchange link below for a more detailed introduction of the background of this conjecture. Note that, since T(n,k) can divide properly T(n-1,A001175(k)), this eventual period of {F^(n)(x) mod k} for sufficiently large n is not necessaily equal to A235249(k), the fixed point when A001175 is iterated with starting value k.

V3-017650 | OEIS-A395802

Minimum number of cells in a connected enclosing shell of an n-cell connected hole on the trihexagonal (3.6.3.6) Archimedean tiling.

Conjecture (UNVERIFIED, matches a(1..22)): a(n) grows as sqrt(18*n); equivalently the largest hole an s-cell shell can enclose is floor((s^2 + 6)/18), and the achievable shell sizes are 5, 11, and the odd integers >= 15 (so 7, 9, and 13 never occur). Each value is established as minimal over holes lying within a bounded region of the 3.6.3.6 tiling; that the region is large enough to exclude a smaller shell arising from a larger hole is supported by a wider-region check but not proved, so global minimality is conjectured. (End)

V3-017657 | OEIS-A395909

Triangle read by rows: row n gives marks on lexicographically earliest n-mark optimal ruler.

A ruler is optimal if it is perfect and no perfect ruler with the same number of segments has a greater length. Optimal rulers are rare. There are 155050 perfect rulers with length in [0, 123], but only 74 optimal rulers in this range. No blueprint for these rulers is known. It has been conjectured by the author that an optimal ruler with more than 13 segments is either a Wichmann ruler or the mirror image of a Wichmann ruler. For more definitions and references see A103294; more optimal rulers can be found under the Luschny link.

V3-017658 | OEIS-A395970

Lexicographically earliest sequence of nonprime terms such that a(n) shares a factor with exactly n other terms.

There appears to be no easy method of generating each a(n) other than choosing the earliest semiprime that satisfies the condition that it can share with n other terms while not violating the same criteria for all other terms it may share a

factor with. To achieve this when a prime appears as a factor for the first time one must track the number of subsequent terms that must contain that as a factor so that a(n) can be satisfied. Each time that prime appears as a factor in subsequent terms that number is decremented; when it reaches zero no further terms can contain that prime as a factor. When a candidate semiprime is considered one must calculate the number of required terms still to come that must contain its primes as factors, and add to that the number of terms that have already appeared that contain these primes as factors. If that sum equals n then that implies the candidate semiprime can be satisfied so it can be chosen as the next term. Typically the sum will be less than n, implying that the primes for the candidate will not be able to be chosen as factors of subsequent terms before the candidate term has shared with n other terms. In this case the next lowest semiprime candidate must then be trialled. For the terms studied it appears this method never allows the square of primes to be terms, and it conjectured this is true for all n>1.

V3-017677 | OEIS-A396456

Smallest prime greater than the n-th prime-complete number.

A double (two prime-complete numbers in one prime gap) occurs only for the shared next-primes 37, 97, 487, and 4621; no further double exists below 10^12, and a heuristic based on the density of prime-complete numbers suggests this list of doubles is complete and that no triple occurs. That is, the counting function for prime-complete numbers, A377028(n) - 1, grows sub-polynomially (empirically exp(O(sqrt(log n)))), so prime-complete numbers thin out faster than any polynomial while prime gaps grow only logarithmically. The expected number of further doubles beyond x is therefore a convergent sum, supporting the conjecture that the complete list of doubles is 37, 97, 487, 4621.

V3-017683 | OEIS-A396596

Natural numbers k such that the sum of the x-th powers of the divisors of k achieves a record, for some x <= 0.

This sequence includes the highly composite numbers (A002182) for which x = 0; the superabundant numbers (A004394) for which x = -1; and the deeply composite numbers (A095848) for which x << 0. We note that superabundant numbers less than 10^11 are either highly composite or deeply composite, or both. We conjecture that the present sequence can be constructed simply as a union of highly composite numbers and deeply composite numbers. All terms must be the least of their prime signature (A025487). The intersection of the above sequences is A095849. The conjecture above is false. For example, A004394(75) = 13974537376800 is superabundant, and like all terms of A004394, qualifies as a term of this sequence. However, it is neither highly composite (A002182) nor deeply composite (A095848); and there are other such terms. This is the least counterexample with x = -1. It would be interesting to know the least counterexample for any x < 0. This makes the production of additional terms of this sequence more difficult, because records could be set for the sum of the x-th powers of the divisors of k where k is neither highly composite nor deeply composite. - _Hal M. Switkay_, Oct 05 2026

V3-017692 | OEIS-A396722

a(n) = (4^n/2) * p(n, 5/2), where p(n,x) is the Lagrange interpolating polynomial through (1,0) and (k,1) for k=2..n+1.

The recurrence conjectured by _R. J. Mathar_ on Jun 30 2026 follows directly from the interpolation conditions. Let p(n,x) be the polynomial in the definition. For n >= 1, we have n*p(n,x) = (n+1-x)*p(n-1,x) + x-1, since both sides are polynomials of degree at most n that agree at x = 1, 2, ..., n+1. Evaluating this at x = 5/2 and using a(n) = 4^n*p(n,5/2)/2 yields n*a(n) - (4*n-6)*a(n-1) = 3*4^(n-1). For n >= 2, subtracting four times this exact identity (with n replaced by n-1) gives n*a(n) - (8*n-10)*a(n-1) + (16*n-40)*a(n-2) = 0, proving the conjecture. - _Eiver Rodríguez_, Sep 28 2026 Conjecture D-finite with recurrence n*a(n) +2*(-4*n+5)*a(n-1) +8*(2*n-5)*a(n-2)=0. - _R. J. Mathar_, Jun 30 2026

V3-017716 | OEIS-A396884

Number of distinct smallest connected polyiamonds that contain every free n-iamond, up to rotations, reflections and translations of the triangular lattice.

No closed form or low-order recurrence is known for the nine listed terms (conjectured to have none, UNVERIFIED). The listed values are the number of minimum-size containers found within a finite search window whose width equals n (forced by the straight n-iamond) and whose height grows as max(4, floor((n+2)/3)); global minimality over all bounding boxes is conjectured but not separately certified.

V3-017720 | OEIS-A396960

Conjectured list of numbers whose trajectory under the 15x+1 map eventually reaches 1, where the map sends odd x to 15x+1 and even x to x/2.

Conjectured list of numbers whose trajectory under the 15x+1 map eventually reaches 1, where the map sends odd x to 15x+1 and even x to x/2. "Conjectured" in the same sense as A267703: every term shown provably reaches 1, but it is conjectural that the numbers not shown never do (a trajectory might in principle descend after exceeding the search bound). Heuristically each odd step multiplies by about 15/4 on average, so almost all positive integers should have divergent trajectories and this sequence should have density 0; neither statement has been proved (Kontorovich and Lagarias state the corresponding claim for the 5x+1 map as a conjecture). - _Karan Sharma_, Oct 03 2026 Conjecturally the number of terms <= X grows like X^(c+o(1)) with c = 0.13100579683..., the root in (0,1) of 15^(c-1) = 2^c - 1. Equivalently, c is the maximum over 0 < b < 1/L of (H(b) - b*L)/(1 - b*L), where L = log_2(15) and H(b) = -b*log_2(b) - (1-b)*log_2(1-b); the maximum occurs at b = 1/(1 + 15^(1-c)). The root equation comes from a branching-process model of the tree of preimages of 1; cf.

Kontorovich and Lagarias for stochastic models of this kind for the 5x+1 map. There are 57, 87, 123, 182 terms <= 10^4, 10^5, 10^6, 10^7, respectively. - _Karan Sharma_, Oct 03 2026

V3-017746 | OEIS-A397258

Indices of late birds in Buss's sequence B = A067836: numbers m such that all smaller primes have occurred before B(m).

To tackle Buss's conjecture (cf. A067836), it is useful to know what are the smallest primes that have not yet appeared up to a given point. They are given in A397259, and here we list the indices where they appear. It might seem more natural to consider "terms" rather than "primes" in the name. Conjecturally (i.e., if B lists all and only primes), the two are equivalent, i.e., this is the list of m such that B(k) >= B(m) for all k > m (and we know that equality is excluded). But if the conjecture isn't true, we can never know whether a smaller composite number might appear somewhere later in B. With the present definition, we know at once and for sure when a term can be listed.

猜想/问题提及段 | historical_or_current_mention_unreviewed | _M. F. Hasler_, Jun 22 2026 | 2026-10-24

关键词命中原段；序列定义见题名及原页面 | 原始来源 | CC BY-SA 4.0

V3-017747 | OEIS-A397259

Late birds in Buss's sequence B = A067836: primes B(m) such that all smaller primes have appeared earlier.

To tackle Buss's conjecture (i.e., all and only primes appear in B = A067836), it is useful to know what are the smallest primes that have not yet appeared up to a given point. These are listed here, while the indices where they appear are given in A397258. Conjecturally this is equivalent to say that we list terms a(n) = B(m) such that B(k) > B(m) for all k > m. But we prefer the chosen definition because it makes the sequence unambiguously defined (and finite, in case one prime would never appear in A067836).

V3-017758 | OEIS-A397369

a(n) = 64^n * [z^n] 2F1(1/4, 1/4; 1; z)^3.

Conjecturally, for every prime p == 1 (mod 4) and all m,r >= 1, a(m*p^r) == a(m*p^(r-1)) (mod p^(4*r)). The exponent is sharp: a(5) - a(1) = 5^4*43524, with 5 not dividing 43524. (The split restriction p == 1 (mod 4) mirrors the mixed-CM result of arXiv:2605.19773; the full depth-(4r) tower mirrors arXiv:2606.15462.) Conjecturally the exponent 4 is governed by the weight-5 control form C = (eta(tau)^12/eta(2*tau)^6)*(2*E_2(2*tau) - E_2(tau)), and the restriction p == 1 (mod 4) by the eta multiplier of self-Hecke modulus 4 and its 3/4-shifted Fourier lattice at the second cusp.

V3-017792 | OEIS-A397903

a(n) is the minimum number of terms in a representation of prime(n) as a sum of distinct primes, each of which is itself recursively representable as a sum of distinct primes. The recursion starts with 2 and 3. a(n)=0 if no such representation exists.

So, based on the conjecture (see A124867) - "Every number n > 17 is the sum of 3 distinct prime numbers" - we can propose the following hypothesis: Conjecture: for all n > 9, a(n) = 2 or 3. This conjecture has been verified up to 10000.

V3-017799 | OEIS-A398139

Numbers m such that the distinct prime factors of the product m*(m+1)*(m+2) are consecutive primes beginning with 2 (that is, the product is a term of A055932).

Conjecture: There are no more terms in this sequence past 440. This conjecture is based on analysis of the growth rate of the minimum prime index values of the GPF of M_3(m) (call it iota_min(M_3(m))) in primorial intervals, such that P_r <= M_3(m) < P_(r+1). For intervals r=2 through r=22 the iota_min progression is: 2, 3, 3, 4, 4, 5, 6, 10, 8, 10, 13, 13, 16, 16, 20, 22, 26, 24, 30, 31, 39. The significance of iota_min in these intervals is that the maximum value of omega for M_3(m) in these intervals is r, so if iota_min exceeds r, it is impossible for there to be a prime-complete product in the interval. In the sequence above, iota_min exceeds r for r=14 and above. The links to the program and output data for this analysis are below.

V3-017800 | OEIS-A398140

Numbers m such that the distinct prime factors of the product m*(m+1)*(m+2)*(m+3) are all consecutive primes beginning with 2 (that is, the product is a term of A055932).

Conjecture: There are no more terms in this sequence past 63. This conjecture is based on analysis of the growth rate of the minimum prime index values of the GPF of M_4(m) (call it iota_min(M_4(m))) in primorial intervals, such that P_r <= M_4(m) < P_(r+1). For intervals r=3 through r=27 the iota_min progression is: 3, 3, 4, 6, 7, 6, 8, 9, 11, 13, 14, 14, 21, 23, 27, 29, 33, 38, 31, 38, 62, 63, 72, 81, 73. The significance of iota_min in these intervals is that the maximum value of omega for M_4(m) in these intervals is r, so if iota_min exceeds r, it is impossible for there to be a prime-complete product in the interval. In the sequence above, iota_min exceeds r for r=15 and above. The links to the program and output data for this analysis are below.

关键词命中原段；序列定义见题名及原页面 | 原始来源 | CC BY-SA 4.0

V3-017805 | OEIS-A398186

a(n) = (1/n) * Sum_{k=0..n-1} A000897(k) * A000897(n-1-k), where A000897(k) = (4*k)!/((2*k)!*k!^2).

Sum_{n>=1} a(n)*x^n is the antiderivative vanishing at x = 0 of the hypergeometric square 2F1(1/4, 3/4; 1; 64*x)^2. Under the change of variable x = t/(1 + 64*t), where t = (eta(2*z)/eta(z))^24, it becomes D^(-1) C_4, where D = q*d/dq and C_4 is the weight-4 meromorphic modular form on Gamma_0(2) associated by Bönisch, Duhr and Maggio with a hypergeometric K3 family. Since x = q - 40*q^2 + ... has integer coefficients and linear coefficient 1, it has a compositional inverse over the integers. Hence the integrality of a(n) is equivalent to the denominator-one divisibility n | c_4(n). This strengthens the depth-one magneticity conjecture for C_4 and is proved in the Shvets reference below.

V3-017807 | OEIS-A398223

a(n) is the number of iterations for the map f(k) = k/3 if k == 0 (mod 3), 4k+1 if k == 1 (mod 3), 2k-1 if k == 2 (mod 3), to first reach a previously-visited value, starting from k=n.

This is a three-branch analog of the Collatz (3x+1) map, branching on residue mod 3 instead of mod 2. Empirically (not proved), every trajectory eventually reaches one of exactly two cycles: (1, 3, 5, 9) and (7, 11, 17, 19, 21, 29, 33, 51, 57, 77, 153). It is conjectured, but not proved, that no starting value diverges to infinity. Verified by direct computation for all n from 1 to 10^6 with no divergences and no cycles other than the two listed. Some trajectories transiently reach very large intermediate values (on the order of 10^15 or more) before collapsing into a cycle.

V3-017810 | OEIS-A398282

Let Ab_k be the set of abelian groups of order k, M_k the set of rings Z/mZ such that phi(m) = k, and let f_k : M_k -> Ab_k be the map such that f_k(Z/mZ) = (Z/mZ)*, the group of units of Z/mZ. a(n) is the least r such that f_k is injective for k = p*2^r, p the n-th prime. a(n) = -1 if no such number exists.

The map f_k can be considered as a refinement of Euler's phi function. For example, we may define another map g_k: Z -> Z where g_k(m) = phi(m) = k, i.e. the map mapping all m to their totient value. The image of g_k is obviously the singleton {k}; g_k is trivially surjective, and Carmichael's conjecture is that it is never injective. Since the image of f_k contains those unit groups (Z/mZ)* such that |(Z/mZ)*| = k, f_k exhibits richer mapping properties.

V3-017815 | OEIS-A398367

Values written by the walker in the trampled carousel process.

Empirically, the ratio L(k+1)/L(k) appears to converge to 1+x = 1.6573427020515763..., where x is the unique positive solution of x = Sum_{m>=2} (1/m) * Sum_{t=binomial(m,2)..binomial(m+1,2)-1} (1+x)^(-t); the last ratio in the computed range is 69020473/41645264 = 1.65734266..., which agrees with 1+x to 8 significant digits. The mean value written during greater-than-1 phase k appears to approach 1/x^2 = 2.3142821659504142717501025363582... (Conjectured.) The conjectured equation for x has an equivalent formulation in terms of Ramanujan's theta function. Let psi(q) = Sum_{n>=0} q^(n*(n+1)/2) = Product_{n>=1} (1-q^(2*n))/(1-q^(2*n-1)) and set q = 1/(1+x). Then the equation for x is equivalent to (1/2)*Integral_{t=0..q} (psi(t)-1)/t dt = 2-1/q. Indeed, if S(q) = Sum_{m>=2} q^binomial(m,2)/(m*(m-1)), then 2*q*S'(q) = psi(q)-1, and the conjectured equation for x is equivalent to S(q) = 2-1/q. The convergence to this solution is still conjectural. Both conjectures are true (see Epstein link). - _Andrew R. Epstein_, Sep 24 2026

关键词命中原段；序列定义见题名及原页面 | 原始来源 | CC BY-SA 4.0

V3-017826 | OEIS-A398589

Irregular triangle read by rows, where row n is the lexicographically earliest sequence starting with T(n,1) = n, allowed integers are >= n, and each term T(n,k) is banned for the next T(n,k) terms in that row. If the sequence for row n is eventually periodic, the row terminates at the end of the first period; however, if it is not eventually periodic, the row is infinite.

Conjecture: There are no values of n > 2 that have rows without a pre-periodic block. Conjecture: All of the rows in this sequence are eventually periodic. It has been shown by Martin Fuller that for n up to 100 this conjecture holds true (see Weinstein link).

V3-017830 | OEIS-A398693

Cardinality of the unique largest subdirectly irreducible factor of the lattice of partitions of n under the dominance order.

The set of partitions of n can be given a complete lattice structure as first shown by Brylawski. This lattice has an irredundant decomposition as a subdirect product of subdirectly irreducible factor lattices; for n >= 13, there is a unique largest factor lattice in this decomposition, the size of which is a(n). For n < 13 the subdirectly irreducible factors of highest cardinality are not always unique and have a different structure not fitting the size formula conjectured to hold below. Conjecture: a(n) = A000041(n) - 4*n + 7 - (-1)^n (verified for n <= 60).

关键词命中原段；序列定义见题名及原页面 | 原始来源 | CC BY-SA 4.0

V3-017835 | OEIS-A398916

a(n) is the Grundy value of "Bit Deletion" game at state n (see comments).

Conjecture: There are no terms exceeding 3. The first occurrences for the integers not exceeding 3 are: a(0) = 0; a(1) = 1; a(2) = 2; a(5) = 3. All n not exceeding 5*10^6 have been checked without finding a term for which a(n) > 3. The conjecture above is true; see the Theorem in the Formula section. - _Maxim Mikhisor_, Sep 07 2026 a(1) = 1. Inductive hypothesis: suppose that we have a(2^k) = (k mod 2) + 1. The binary expansion of 2^(k+1) is 1 followed by k+1 zeros. Thus, the only states reachable from a(2^(k+1)) are a(0) (by removing the leading 1) and a(2^k) (by removing any of the zeros). By the Sprague-Grundy theorem, we have a(2^(k+1)) = mex{a(0), a(2^k)} = mex{0, (k mod 2) + 1} = ((k+1) mod 2) + 1. Conjecture: a(n) = a(4n) for all n. If this conjecture is true, then the sequence a(n*2^k) for a fixed n and increasing k has a period dividing 2: a(n), a(2n), a(n), a(2n), ... All n not exceeding 10^6 have been checked without any

counterexamples to the conjecture found. Consequently a(n) <= 3 for all n, and a(n) is unchanged when any zero-run is altered by an even amount; in particular a(4n) = a(n), which proves both conjectures above. Also a(n) is odd iff n has an odd number of binary digits, and a(n) >= 2 iff m is odd. (End)

V3-017874 | OEIS-A400127

Least m such that every binary word of length n occurs as a contiguous subword of the binary representation of 3^k for some 0 <= k <= m.

Conjecture: a(n) is finite for every n. This conjecture follows from the density of the fractional parts of k*log_2(3). Choose a binary de Bruijn sequence of order n, linearized and rotated to begin with 1. Since log_2(3) is irrational, infinitely many powers 3^k have this finite binary string as their initial digits. Such a power alone therefore contains every n-bit binary word, proving a(n) < infinity for every n. - _David Rabahy_, Oct 04 2026

V3-017886 | OEIS-A400486

Number of positive integers m < 2^n - 1 such that the Collatz trajectories of m and m+1 meet within n steps, after equal numbers of halving steps and before either reaches 1.

Gao tabulated a(n)/2^n to three decimals for 4 <= n <= 24 (Table 3, from 0.063 to 0.389), proved that a(n)/2^n is nondecreasing, that is, a(n+1) >= 2*a(n) (his Corollary 2, from his Lemma 2), and conjectured that a(n)/2^n -> 1. Lagarias's annotated bibliography records the conjecture in another form: the set of m such that f^k(m) = f^k(m+1) for some k <= log_2(m) has natural density 1. A meeting within log_2(m) steps is always a coalescence in Gao's sense, so this form implies a(n)/2^n -> 1.

V3-017887 | OEIS-A400487

Number of positive integers k < 2^n that take the same number of Collatz steps to reach 1 as k-1 or k+1.

Wu (1992) computed a(n) for n <= 24, observed that a(n)/(2^n-1) increases with n, and conjectured that the proportion of integers lying in such runs tends to 1. If a(n)/2^n -> 1, then the positive integers that reach 1 have natural density 1, because every k counted reaches 1. Whether they do is an open problem; the best known lower bound for the number of k <= x that reach 1 is x^0.84 (Krasikov and Lagarias).

V3-017889 | OEIS-A400584

Irregular triangle read by rows: T(n,k) is the number of labelings of the internal vertices of the complete plane binary tree of depth n by + or min, with every leaf equal to 1, that evaluate to k at the root (n >= 1, 1 <= k <= 2^n).

A labeling has root value 1 exactly when it contains a root-to-leaf path whose internal vertices are all min. Choosing the leftmost such path gives a product decomposition of this class. This decomposition proves the product identity conjectured by Peter Bala in A076628 (Feb 11 2015); see Mendonça (2026), technical note linked below. Auffinger and Cable report unpublished work of Albert Chen proving that the root-value probabilities decrease with k, independently discovered by Tam Cheetham-West. Here monotonicity must be understood in the weak sense, since the first two rows contain ties. Conjecture: T(n,k) > T(n,k+1) for n >= 3 and 1 <= k < 2^n. This strict-monotonicity conjecture has been verified by exact computation for 3 <= n <= 12, but is not proved in general.

V3-017894 | OEIS-A400795

Strongly nontriangular numbers, defined as the complement of the generalized triangular numbers in the reference below. Generalized triangular numbers include 1 and those in the range of the function P(i,j) = (i*j+i+j-gcd(i,j))/2 for integers i, j > 1.

It is conjectured that this sequence is infinite and has natural density zero. The sequence arises in an attempt to study "generalized triangular numbers" of the form P(i,j) = (i*j+i+j-gcd(i,j))/2. This formula counts the number of lattice points in the triangle with vertices (0,0), (i,0), (0,j), excluding points on the hypotenuse.

Linear equation with primes

Is there an integer n with an infinite number of representations of the form $n=2q-p$, where p and q are both primes? Given a positive integer $k>1$, I would like to know for which (if any) integers n the linear equation $q-kp=n$ admits an infinite number of solutions, where p and q are primes. (I'm not including $k=1$ because it reduces to well know open problems, $k=1$ and $n=2$ would be the twin primes conjecture) The density of the prime numbers implies that at least there are integers n with an arbitrarily large number of representations.

Actions on $\mathbb{H}^n$ generated by torsion elements

Let n be a large integer. I am looking for a cocompact properly discontinuous isometric action on n-dimensional Lobachevky space which is generated by elements of finite order. Or equivalently, I need a cocompact properly discontinuous isometric action $\Gamma\curvearrowright\mathbb{H}^n$ such that $\mathbb{H}^n/\Gamma$ is simply connected, here $\mathbb{H}^n/\Gamma$ stays for quotient space (NOT for orbifold). Comments. I am aware that for large n these is no cocompact action generated by reflections (Vinberg, 1984). Consider the group of matrices with integer coefficients from $\mathbb{Q}[\sqrt{5}]$ which preserve the quadratic form $$\tfrac{1+\sqrt{5}}{2}\cdot x_0^2-x_1^2-\cdots-x_n^2.$$ This gives cocompact properly discontinuous isometric action, say $\Gamma\curvearrowright\mathbb{H}^n$. (For $n=2$, the group Γ contains the Coxeter group of regular right-angled pentagon.) I would be very happy if the subgroup generated by the elements of finite order in Γ would have finite index. Or, equivalently, if $$|\pi_1(\mathbb{H}^n/\Gamma)|<\infty.$$ P.S. It seems that examples of such actions are not known. (In addition to Agol's comment, I've got a letter from Vinberg stating this.)

Solving NP problems in (usually) Polynomial time?

Just because a problem is NP-complete doesn't mean it can't be usually solved quickly. The best example of this is probably the traveling salesman problem, for which extraordinarily large instances have been optimally solved using advanced heuristics, for instance sophisticated variations of branch-and-bound. The size of problems that can be solved exactly by these heuristics is mind-blowing, in comparison to the size one would naively predict from the fact that the problem is NP. For instance, a tour of all 25000 cities in Sweden has been solved, as has a VLSI of 85900 points (see here for info on both). Now I have a few questions: 1) There special cases of reasonably small size where these heuristics either cannot find the optimal tour at all, or where they are extremely slow to do so? 2) In the average case (of uniformly distributed points, let's say), is it known whether the time to find the optimal tour using these heuristics is asymptotically exponential n, despite success in solving surprisingly large cases? Or is it asymptotically polynomial, or is such an analysis too difficult to perform? 3) Is it correct to say that the existence of an average-case polynomial, worst-case exponential time algorithm to solve NP problems has no importance for P=NP? 4) What can be said about the structure of problems that allow suprisingly large cases to be solved exactly through heuristic methods versus ones that don't?

Artin-Schreier Theorem for Rings

This has been in my mind for quite some time. Looking at the Artin-Schreier Theorem for fields: If L is a field and K its algebraic closure and if $1< [K:L] < \infty$ then $K=L[i]$ and L is a real closed field. (Thus L has characteristic 0. Here i is just the square root of -1). I was wondering if a "generalized" Artin-Schreier exists or if someone could refer to me to some paper that attempts this. There is a concept of real closedness and "algebraic closedness" of reduced commutative rings, but I doubt that the statement would hold. So one

has the following conjecture: If L is a reduced commutative ring and K is its total integral closure (this is an equivalent notion of algebraic closure if K and L were fields) and if $1<[K:L]< \infty$ (here I mean that K is a finite L-module that is not the same as L) then L is real (thus its characteristic is 0, and one can add that L is real closed in the sense of reduced commutative rings). Can one easily show this, even at least prove that L has characteristic 0?

Sums of Strongly z-ideals

In the rings of continuous functions,i.e.$(C(X))$ an ideal I is called strongly z-ideal if it is an intersection of some maximal ideals of $C(X)$. i.e. $$I=\cap_{\alpha \in A} \mathcal{M_{\alpha}}$$ Where each $\mathcal{M_{\alpha}}$ is a maximal ideal of $C(X)$. Question: If I and J are two strongly z-ideals of $C(X)$, Is the ideal $I+J$ strongly z-ideal or all of $C(X)$? PS: If X is a P- space, then each ideal of $C(X)$ is strongly z- ideal, And conversly if each ideal of $C(X)$ is strongly z- ideal than X is a P-space.

Minimizing the excursion of a sum of unit vectors

I have n unit-length vectors v_i in $\mathbb{R}^3$, whose sum is zero: $$ v_1 + v_2 + \cdots + v_n = 0 \; .$$ Now I form the closed polygon P in space by placing them head to tail. So the vertices of P are $$ 0, v_1, (v_1+v_2), \ldots, (v_1+\cdots +v_{n-1}), 0 \; .$$ My question is: What is the minimum excursion from the origin achievable by shuffling the vectors by a permutation of $(1,2,\ldots,n)$? For example, the 12 red vectors below wander $\sqrt{10}$ from the (purple) origin, but the light blue vectors-the same in a different order-stay within $\sqrt{3}$. (These particular vectors derive from the vertices of a cuboctahedron, so some are negations of others.) Is there some constant $r_{\min}$ independent of n such that the sum can always be arranged to be at most $r_{\min}$, i.e., lie within an origin-centered ball of that radius? Or must $r_{\min}$ depend on n? Is there some natural algorithm for minimizing the excursion, or must I (in the worst case) try all $n!$ permutations? Of course the same question can be asked in any dimension $\mathbb{R}^d$, but my focus is $\mathbb{R}^3$. Thanks for ideas and/or pointers! Update1. The suggestion (in the comments) that $r_{\min} = \sqrt{d}$ in $\mathbb{R}^d$, based on an answer to the previous MO question, "Bounding a signed sum of complex numbers," is intriguing, and may be true. But I do not see that it is proved by that answer. Update2. With key phrases suggested by Nik Weaver, I found a 1981 paper by Imre Bárány, "A Vector-Sum Theorem and its Application to Improving Flow Shop Guarantees" (Math. Oper. Res. link), which shows that $r_{\min} < \frac{3}{2} d$.

Splitting Pythagorean triples

Can one partition the set of positive integers into finitely many Pythagorean-triple-free subsets? If so, what is the smallest number of such subsets? Taking a wild guess, I would be least surprised if the answer were 3. Notice that the 2 subsets of integers such that highest power of 5 that divides them is a) even b) odd manage to split most primitive triples, plus all the multiples of those. Notice also that Schur proved the positive integers cannot be split into any finite number of sum-free subsets (i.e. no finite partition can split all power-of-1 Fermat triples), while Fermat's theorem proves that all power-of-n (n>2) triples can be split by the trivial partition into 1 set. Edit: Since this turns out to be a known open problem, we're adding the tag [open-problem] and converting this question to community wiki. The idea is to have a separate answer for each possible approach to solving this problem. If you have some additional insight or a reference to contribute to an answer, you only need 100 rep to do so. We're still figuring out exactly how to handle open problems on MO. The discussion is happening on this tea.mathoverflow.net thread.

The Class Number One Problem for Real Quadratic Fields

An approach to the Gauß class number one problem for imaginary quadratic fields is to determine the integral points on the modular curve $Y_{nonsplit}(n)$ for a suitable n. Here follows a quick summary, but see Appendix A in Serre's book "Lectures on the Mordell-Weil Theorem" for more details: Given an imaginary quadratic K of class number 1, one considers an elliptic curve E with CM by O_K, which is unique up to $\mathbb{C}$-isomorphism. Its j-invariant lies in $\mathbb{Z}$. Given any integer n, all of whose prime divisors are inert in K, our E yields a unique integral point on $Y_{nonsplit}(n)$. That means, fixing an n and letting p be its largest prime divisor, any imaginary quadratic K of class number 1 whose discriminant is larger than $4p$ in absolute value will furnish a unique integral point on $Y_{nonsplit}(n)$. Hence, determining the integral points on $Y_{nonsplit}(n)$ for one n for which there are finitely many integral points solves the problem. Heegner used $n=24$, as did Stark. My question is whether a similar approach has been, or can be, used in the real quadratic case; the goal being to prove that there are infinitely many such fields of class number one. For what it's worth, here's what would happen in my pipe dream: To a real quadratic K of class number 1 one attaches uniquely an abelian surface (or some other kind of object) with real multiplication by O_K; One shows that this object gives rise to a unique rational point on some moduli space, and conversely, all such rational points would come from a K; ($Y_{nonsplit}$ plays this role in the imaginary case...) One shows that the moduli space has infinitely many rational points. (Since this is a well-known open problem, I'll follow the advice of the FAQ and make it community-wiki. I am a little embarrassed asking such a speculative question, but I also feel that speculation drives a lot of mathematical research.)

Kronecker's Jugendtraum for real quadratic fields?

Kronecker's Jugendtraum (or Hilbert's 12'th problem) is to find abelian extensions of arbitrary number fields by adjoining `special' values of transcendental functions. The Kronecker-Weber theorem was the first realisation of this: i.e. $\mathbb{Q}^{ab}=\mathbb{Q}^{cycl}=\mathbb{Q}(e^{2\pi i \mathbb{Q}})$. If K is an imaginary quadratic field, then the theory of complex multiplication realises Kronecker's dream: roughly $K^{ab}=K(j(\tau), \wp(\tau,z))$, where τ is a `special' value of the upper half plane corresponding to an elliptic curve $E\cong\mathbb{C} / \Lambda$ with complex multiplication by the ring of integers of K, and $z \in \Lambda \otimes \mathbb{Q}$ (this is like adjoining $j(E)$ and the x-coordinates of the torsion points of E). Is there some class of special analytic functions, and some special kind of objects which conjecturally play the role of the j-function, the $\wp$-function and CM elliptic curves for real quadratic fields?

Almost Complex Structures: 'Tame' versus 'Compatible'

Consider a symplectic manifold (M,ω) and the space of almost complex structures. These are $J:TM\to TM$ with $J^2=-\text{id}$. A given J is ω-tame when $\omega(v,Jv)>0$, and J is ω-compatible when it is ω-tame and $\omega(J\cdot,J\cdot)=\omega(\cdot,\cdot)$. The set of either such J forms a contractible subspace. Note that in either scenario we can form a Riemannian metric g_J by twisting ω in some way with J. In practice, I sometimes see J being tame, and more often I see J being compatible, but in either case I am unsure of the restrictions that each imposes. Is there any context in which it is necessary/helpful to use one condition over the other? This need not be related to pseudo-holomorphic curves in Floer theory. Do certain results fail when I relax "compatible" to "tame"? A fundamental difference I see (quoted from McDuff-Salamon's big textbook) is that compatible J minimize the energy of a J-holomorphic curve in its homology class, but not necessarily for tame J.

Measures of full Hausdorff dimension for self-affine sets

Consider the iterated function system $T_{1}(x)=(\beta x,\tau y)$, $T_{2}(x,y)=(\beta x+(1-\beta),\tau y+ (1-\tau))$ for $\beta\in(1/2,1)$ and $\tau\in (0,1/2)$ with self affine set $\Lambda_{\beta,\tau}$. It is known that for almost all β and all τ $\dim_{H}\Lambda_{\beta,\tau}=\dim b=1-\log(2\beta)/\log(\tau)$ where $b=(1/2,1/2)$ is the Bernoulli measure on Λ. Essential this is due to the fact that the projection of b to the x-axis is an infinite Bernoulli convolution which is know to be generic absolutely continues (Solomyak theorem). On the other hand we have shown that if β^{-1} is a Pisot number we have $\dim b<\dim_{H}\Lambda_{\beta,\tau}<1-\log(2\beta)/\log(\tau)$ for all Bernoulli measures b. The projection of all b in this case is singular with a dimension drop (Erdös theorem). Now here comes the question: Is there a (ergodic) measure of full dimension and what is $\dim_{H}\Lambda_{\beta,\tau}$ in the later case?

Is $Q_n(x)=\sigma_{n+1}(x)/\sigma_n(x)$ logarithmically convex on $\mathbf{R}$?

In 1975 J. van de Lune considered the monotony properties of the canonical Riemann Upper and Lower sums for $\int_0^1 t^xdt$, with $x>0$. Writing $\sigma_n(x) := 1^x+2^x+\cdots+n^x$ these sums are $$U_n:=U_n(x)=\sigma_n(x)/n^{x+1} \quad \text{and}\quad L_n:= L_n(x)=\sigma_{n-1}(x)/n^{x+1}.$$ He proved (by mathematical induction) that $U_n>U_{n+1}$ and $L_n<L_{n+1}$. A later proof of $U_n>U_{n+1}$ was obtained by showing that the function $$h(x):= h_n(x)=(\sigma_{n+1}/\sigma_n(x))(n/(n+1))^x$$ is strictly decreasing on all of $\mathbf{R}$. Soon afterwards he came to realize that the monotonicity of $h(x)$ would be

a consequence of the logarithmic convexity of $Q(x):=Q_n(x)=\sigma_{n+1}(x)/\sigma_n(x)$ on all of $\mathbf{R}$. Various numerical tests on $Q(x)$ were performed, but no proof was found. Another application: From the logarithmic convexity of $Q(x)$ one may also obtain a simple proof of a conjecture made by H. Alzer and A. A. Jagers: $$f(x):=f_n(x)=\Bigl(\frac{\frac{1}{n+1}\sigma_{n+1}(x)}{\frac1n \sigma_n(x)}\Bigr)^{1/x}$$ is strictly increasing for $x>0$. Question: Is for every (fixed) integer $n\ge2$, the function $$x\in\mathbf{R}\mapsto Q_n(x):=(1^x+2^x+\cdots+n^x+(n+1)^x)/(1^x+2^x+\cdots+n^x)$$ logarithmically convex on all of $\mathbf{R}$?

The oriented homeomorphism problem for Haken 3-manifolds

Haken famously described an algorithm to solve the homeomorphism problem for the 3-manifolds that bear his name (fleshed out by many others, including Hemion and Matveev who fixed some gaps). But it's often natural to consider 3-manifolds equipped with an orientation, and so my question is: Question 1: Is there an algorithm in the literature that determines whether or not a pair of oriented Haken 3-manifolds M and N are orientedly homeomorphic? By Haken's Algorithm, we can reduce to the case in which M and N are (unorientedly) homeomorphic, and so the question can be reduced to: Question 2: Is there an algorithm in the literature that determines whether or not an orientable Haken 3-manifold M admits an orientation-reversing self-homeomorphism? Notes: Note the words 'in the literature'. I don't really doubt that this algorithm exists, but the details seem quite complicated, particularly in the non-geometric case, so I hope that someone will be able to supply a reference. A very short argument would also be nice. Answers of the form 'I don't know, but I'm sure it can be done if you work out each geometric case individually and then think hard enough about the JSJ decomposition', while appreciated, would be less useful. The hyperbolic case can be deduced from Sela's solution to the homeomorphism problem, which also computes the automorphism group. I've no doubt the other non-Haken cases can be handled similarly. Hence my interest in the Haken case. It may be that a simple modification of Haken's Algorithm handles the oriented case. This isn't at all clear to me, but I would be very interested to hear if it's true. (added later) I would also be happy to confirm that this question is `open' (in the sense that an answer is not in the literature, rather than that the answer is in doubt)---I very much suspect that this is the case. An authoritative pronouncement by someone who knows the literature very well would therefore be a valid answer.

Are Galois groups of Q with restricted ramification supposed to be finitely generated?

Fix a finite set S of places of $\mathbb Q$. Let $G_{\mathbb Q,S}$ be the Galois group of the maximal extension of $\mathbb Q$ unramified outside S$. I believe that it is an open question whether this group is topologically finitely generated, that is, contains a dense, finitely generated subgroup. Is there a standard conjecture about whether $G_{\mathbb Q,S}$ should be finitely generated or not? Has anyone published an opinion? JSE mentions a stronger conjecture: $|S|$ generators suffice; further, the existence of a special set of generators labeled by S and inert at the labeling place. Is this refinement standard? (Note that a finite extension would suffice to disprove this hypothesis.) Weakening the hypothesis, we could restrict the ramification at S to be tame.

Why would dim primitive irrep divide size of some conjugacy class ?

From Isaacs et.al. 2005 Conjecture C. Let χ be a primitive irreducible character of an arbitrary finite group G. Then χ(1) divides | clG(g)| for some element g ∈ G. Here, of course, we have written clG(g) to denote the class of g in G. We have checked that Conjecture C holds for all irreducible characters (primitive or not) of all groups in the Atlas 1. Question 1 What is motivation for this ? Is it possible to describe what conjugacy class(es) should correspond to irreducible representation in this way ? (at least for some standard groups S_n, A_n, GL_n(F_q),...) What are representative examples? Question 2 Is it still open ? The authors write: We now digress to explain our original motivation for considering these questions. There are numerous parallels and analogies between theorems concerning the of set irreducible character degrees of a finite group and theorems concerning the set of conjugacy class sizes of such groups. This suggests that perhaps there are some subtle arithmetic connections between these two sets of integers associated with a given group. One such connection that is easy to see is that each prime number that divides an irreducible character degree of G must also divide some class size of G. If G is solvable, then S. Dolfi showed that more is true. He proved [2] that given any two distinct primes p and q such that pq divides some irreducible character degree of a solvable group G, then pq also divides some class size of G. One might conjecture that the analogous assertion for three or more distinct primes is also true, but as far as we know, this remains open. Partial result: In the following, we use the notation np to denote the p-part of a positive integer n, where p is a prime number. Corollary D. Let χ be a primitive irreducible character of a solvable group G, and let p be a prime divisor of |G|. Then χ(1)p divides (| clG(g)|p) 3 for some element g ∈ G. Not related results, for compltеness: Denote CV(g) fixed point subspace for g in V. Our main result is the following. Theorem A. Let V be a nonzero finite dimensional completely reducible F G-module, where F is any field and G is any finite group. Assume that CV (G) = 0 and let p be the smallest prime divisor of |G|. Then there exists some element g ∈ G such that $ dim CV (g) ≤ (1/p) ~ dim V $. The fraction 1/p cannot, in general, be replaced by any smaller quantity. In particular, this shows that Neumann’s conjecture is valid for odd-order groups, at least... Corollary B. Let V be a nonzero finite dimensional completely reducible F G-module, where F

is an arbitrary field and G is any finite group, and assume that CV (G) = 0. Then $1/ |G| \sum_{g∈G} dim CV (g) ≤ ((p + 1)/ 2p)~~ dim V$, where p is the smallest prime divisor of |G|.

A maximal element, where Schur gives a minimal element

Let me recall a result due to I. Schur, which I learnt from F. Goldberg's answer to my MO question Hadamard-like inequalites for positive definite symmetric matrices. If H is a subgroup of $\frak S_n$ and χ is an irreducible complex character over H, define $$d_\chi(S)=\frac1{\chi(e)}\sum_{g\in H}\chi(g)\prod_{i=1}^ns_{ig(i)}.$$ Then for every $S\in SPD_n$, we have $$\det(S)\le d_\chi(S).$$ Notice that if $H=\frak S_n$ and χ is the signature, then d_χ is the determinant. Thus $\det$ is the smallest element among the d_χ's. If instead $\chi={\bf1}$, then d_χ is the permanent. If $H=(e)$, Schur's inequality is just the Hadamard inequality $$\det S\le\prod_is_{ii}.$$ Given n, there are many distinct d_χ's, even though several choices of the pair (H,χ) yield the same function. For instance, there are only 11 distinct functions if $n=3$, among 13 pairs. My question is whether the permanent is the largest element among the d_χ's. In other words, is it true that for every $S\in SPD_n$, we have $$d_\chi(S)\le{\rm per}(S)\quad ?$$ I checked the truth of this assertion if $n=2$, $n=3$, and also in quite a complicated case of $n=4$, where $H={\frak A}_4$ and $\chi\ne{\bf1}$ is a linear character.

approximate uncertainty principle for finite abelian groups

Edit: we cannot find such an example. It would imply a negative solution to the KS${}_2$ conjecture which has now been proven by Marcus, Spielman, and Srivastava in this paper. In fact, their solution implies that there always exists S such that any f supported on S (or S^c) satisfies $\|\frac{1}{2}\hat{f} - \hat{f}|_T\|_2 \leq O(\sqrt{\epsilon})\cdot\|\hat{f}\|_2$. Can we find, for every $\epsilon > 0$, an example of the following? $\bullet$ a finite abelian group G $\bullet$ a small subset T of the dual group $\hat{G}$ (meaning $|T| \leq \epsilon |\hat{G}|$) such that for any subset S of G, there is a nonzero complex valued function f supported either on S or S^c whose Fourier transform is approximately supported on T (meaning $\|\hat{f} - \hat{f}|_T\|_2 \leq \epsilon \|\hat{f}\|_2$). It seems unlikely, but I don't know any version of the uncertainty principle that would forbid this. Two comments: (1) This arose out of discussions I had with Chuck Akemann about the Kadison-Singer problem. It wouldn't, as it stands, imply a negative solution to Kadison-Singer, but it would be close and (I believe) could probably be easily converted into a full negative solution. (2) Since either S or S^c has cardinality at least $|G|/2$, one could consider assuming $|S| \geq |G|/2$ and demanding that f be supported on S. But I know that this makes the problem too hard. (Given T, I can always find an S with $|S^c|/|G| = O(\sqrt{\epsilon})$ such that no nonzero function supported on S has Fourier transform approximately supported on T.)

Open problems about CMC hypersurfaces with symmetries?

Recently, Andrews and Li announced a complete classification of CMC ($H=const.$) tori in S^3, confirming a conjecture of Pinkall and Sterling. Their main result is that any such torus is rotationally symmetric, and this reduces the problem to a previous classification due to Perdomo, also studied by Hynd, Park and McCuan. [As a side note, some of the techniques used are similar to Brendle's solution of the Lawson Conjecture, that states that the only minimal ($H=0$) torus in S^3, up to congruences, is the Clifford torus $S^1(\tfrac{1}{\sqrt2})\times S^1(\tfrac{1}{\sqrt2})$.] It is also known that there are CMC tori in S^3 that are not congruent to the family $S^1(r)\times S^1(\sqrt{1-r^2})$ of Clifford tori, so, in a certain sense, their only (continuous) symmetries are encoded in an isometric circle action, as confirmed by Andrews' and Li's result. Given this context, my question is: Are there open questions, conjectures, etc., regarding existence or non-existence of CMC hypersurfaces with symmetries in highly symmetric compact manifolds, analogously to the above case of CMC tori in S^3? Actually, I'd be particularly interested in questions regarding non-minimal CMC embeddings ($H=const\neq 0$). To be (slightly) more precise, I am interested in knowing if there are questions of the form "Let (M,g) be a compact manifold with many symmetries (i.e., a "big" Lie group acts isometrically), and consider embeddings of some manifold N into M. Then if $N\subset M$ is CMC, it must have certain symmetries (and perhaps cannot have other symmetries)." In other words, are there any analogues of (or questions similar to) the conjecture of Pinkall and Sterling that CMC tori in S^3 are rotationally symmetric, but for other (perhaps higher dimensional) compact manifolds? Perhaps some of these questions are disguised as questions about Mean Curvature Flow? Notice also that if $N\subset M$ is an orbit of an isometric group action, then it is automatically CMC. However, there could be other CMC embeddings of N into M, not congruent to any orbits (e.g., with less symmetries, as the tori above). Should one expect any general behavior for this other CMC embeddings? Are there any known results, questions or conjectures in this direction? I apologize for the somewhat vague question, but none of the above references seems to risk any further conjectures or indicates natural extensions of their results. Also, a quick google search and inverse citations on MathSciNet don't give much in terms of open questions. I was wondering if there is a reason behind it... Any references to recent survey-type papers related would also be very appreciated!

If all real conjugacy classes are strongly real, then all real irreps are "strongly real"(symmetric), true?

Question Is true that if all real conjugacy classes of a finite group are strongly real, then all its real irreducible representations (irreps) are "strongly real" (symmetric)? And vice versa? Definitions: An irrep is called real if its Frobenius-Schur indicator is either $+1$ or -1, but not 0. An irrep is called "symmetric" ("orthogonal" ("strongly real")) if it has FS-indicator $+1$, which is equivalent to it being possible to realize it over the real numbers. A conjugacy class is called "real" if it is preserved by $g\mapsto g^{-1}$. It is called "strongly real" if it is a product of two involutions. Context It is known that the number of real conjugacy classes is the same as the number of real irreps. A. Knutson asked: Are there “real” vs. “quaternionic” conjugacy classes in finite groups?, i.e., is it possible to split "real" conjugacy classes into two subclasses corresponding to the splitting of irreps. Tim Dokchitser answered that no such splitting may exist in general which will be automorphism covariant .... The question above is weakening A. Knutson's question. It has been asked explicitly in the paper Kulshrestha and Singh - Real elements and Schur indices of a group (MSN, arXiv), where the authors present some positive evidence for the question above. However, their examples do not cover GAP's SmallGroups List. SubQuestion How difficult is it to check this in GAP? (I just installed it, but never played.)

A generalization of Gromov's theorem on polynomial growth

I was sure it is known, but it appears to be an open problem (see the answer of Terry Tao). Assume for a group G there is a polynomial P such that given $n\in\mathbb N$ there is set of generators $S=S^{-1}$ such that $$|S^n|\leqslant P(n)\cdot|S|\ \ (\text{or stronger condition}\ |S^k|\leqslant P(k)\cdot|S|\ \text{for all}\ k\le n) .$$ Then G is virtually nilpotent (or equivalently it has polynomial growth). Comments: Note that typically, $|S|\to \infty$ as $n \to\infty$ (otherwise it follows easily from the original Gromov's theorem). If it is known, then it would give a group-theoretical proof that manifolds with almost non-negative Ricci curvature have virtually nilpotent fundamental group (see Kapovitch--Wilking, "Structure of fundamental groups..."). This proof would use only one result in diff-geometry: Bishop--Gromov inequality. Edit: The actual answer is "Done now: arxiv.org/abs/1110.5008" --- it is a comment to the accepted answer. (Published reference: E. Breuillard, B. Green, T. Tao. The structure of approximate groups. Publ. Math. Inst. Hautes Études Sci. 116 (2012), 115-221. Link under Springer paywall)

Why Donaldson's Four-Six Conjecture?

Simon Donaldson apparently made the following conjecture: Two closed symplectic 4-manifolds (X_1,ω_1) and (X_2,ω_2) are diffeomorphic if and only if $(X_1\times S^2,\omega_1\oplus\omega)$ is deformation-equivalent to $(X_2\times S^2,\omega_2\oplus\omega)$. Here ω is a symplectic structure on S^2, and a deformation-equivalence is a diffeomorphism $\phi:X_1\times S^2\to X_2\times S^2$ such that $\omega_1\oplus\omega$ and $\phi^*(\omega_2\oplus\omega)$ can be joined by a path of symplectic forms. However, where I read this did not contain any background or the original source. Where did Donaldson make this claim? And why did he make this claim? What is the motivation / are there good examples where this holds? Ivan Smith showed (through examples) that this conjecture fails when we replace S^2 by $\mathbb{T}^2$, so the statement itself seems pretty rigid. [Edit] Motivation and examples come from the 1994 paper "Symplectic Topology on Algebraic 3-Folds" of Ruan and the 1997 followup "Higher Genus Symplectic Invariants..." of Ruan-Tian, which states and proves the conjecture for simply-connected elliptic surfaces! And now we're starting to get counterexamples!

Smooth proper schemes over Z with points everywhere locally

This is a variation on Poonen's question, taking Buzzard's fabulous example into account. It was earlier a part of this other question. Question. Is there a smooth proper scheme $X\to\operatorname{Spec}(\mathbb{Z})$ such that $X(\mathbb{Q}_v)\neq\emptyset$ for every place v of $\ \mathbb{Q}$ (including $v=\infty$), and yet $X(\mathbb{Q})=\emptyset$? I believe the answer is No. The evidence is flimsy : X cannot be a curve or a torsor under an abelian variety (Abrashkin-Fontaine) or a twisted form of $\mathbb{P}_n$. I haven't gone through a list of smooth projective $\mathbb{Q}$-varieties which contradict the Hasse principle to check if any of them has good reduction everywhere, but the chances of such a thing are slim. Colliot-Thélène and Xu give a systematic treatement of many known examples of quasi-projective $\mathbb{Z}$-schemes Y such that $Y(\mathbb{Z}_p)\neq\emptyset$ for every prime p and $Y(\mathbb{R})\neq\emptyset$, but $Y(\mathbb{Z})=\emptyset$. Some of these schemes might even be smooth over $\mathbb{Z}$, but none of them is proper. Fontaine's letter to Messing (MR1274493) might be of some relevance here.

Are most cubic plane curves over the rationals elliptic?

%This is a new version of the original question modified in the light of the answers and comments. The word 'most' in the title is ambiguous. The following is one way of making it precise. Question1: (This seems to be open. See Poonen's answer below) A cubic projective

curve over $\mathbb{Q}$ is given by ten relatively prime integers (the coefficients of its equation after clearing the denominators). Suppose we take a ten dimensional box $[-N,N]^{10}$ and choose points with integer coordinates with respect to the uniform measure and form the equation of the associated cubic curve. Suppose the number of points which give rise to a curve with a rational point is $E(N)$. Then what can we say about $E(N)/(2N+1)^{10}$ as $N\rightarrow \infty$? Should the limit exist and if it does, should it be one, zero, or some other number? Another question of interest is: Question 2: (There is a satisfactory answer to this. See Voloch's response below.) Are either of the sets {cubics with no rational point} and {cubics with at least one rational point} Zariski dense?

Intersecting family of triangulations

Let $\cal T_n$ be the family of all triangulations on an n-gon using $(n-3)$ non-intersecting diagonals. The number of triangulations in $\cal T_n$ is C_{n-2} the $(n-2)$th Catalan number. Let $\cal S \subset \cal T_n$ be a subfamily of triangulations with the property that every two triangulations of $\cal S$ have a common diagonal. Problem: Show that $|\cal S| \le |\cal T_{n-1}|$. Remark: This problem was raised independently around the same time by Karen Meagher and by me. Updates (and counter-updates) A few weeks after this problem was posted Gjergji Zaimi (private communication) proposed a more general conjecture: Conjecture: Let P be a polytope with no triangular face. Then the maximum number of vertices such that every two vertices belongs to a common facet is attained by all vertices of a single facet. The original question is the case of the associahedron. The case of the permutahedron is (update: not) known and very interesting. (It is similar in spirit but yet different from a result by Frankl and Deza- and it is related to extremal combinatorics on permutations.) For the cube the result is immediate but can serve as a good starting point for extremal combinatorics (Problem 1 here). Update: Bruno le Floch showed that the more general conjecture is false: He described a quadrangulation of S^2 with 15 vertices and 13 quadrangles having 5 vertices each two on a face. Update Paco Santos proposed the following intermediete conjecture: Conjecture: For every flag simplicial polytope, the maximum size of a set of pairwise intersecting facets is achieved by the facets containing some common vertex. A flag simplicial polytope is a simplicial polytops so that every set of vertices that any two form an edge is the set of vertices of a face. Santos's conjecture thus asserts that the conjecture about polytopes with no triangular faces still applies for dual-to-flag polytopes. Partially motivated by the MO question Jorge Olarte, Francisco Santos, Jonathan Spreer, Christian Stump wrote a paper The EKR property for flag pure simplicial complexes without boundary where they extend the conjecture to flag pure simplicial complexes without boundary and give some evidence for it.

Transcendentality of all irrationals in the Cantor set

Hi, I am a student researcher trying to prove that all irrationals within the Cantor set are transcendental. This is grounded, intuitively, in Cantor set members' being non-normal; since algebraic numbers are widely believed to be normal, this implies the transcendentality of the irrationals in the Cantor set. Now, I am at a dead end in trying to prove this, and I would appreciate any pointers (I will give you full credit in whatever end product comes out of this). I tried recasting the problem in the following way: if I can prove that any irrational algebraic number must have a 1 in its ternary expansion, then the result I'm after follows. With this, I realized that if an irrational algebraic number has at least one 1 in its ternary expansion, then it must have infinitely many of them (because irrational algebraics are a field, and otherwise I could add an appropriate irrational algebraic number and get another irrational algebraic without any 1's in their ternary expansions -- a contradiction). But I can't really get anywhere past this (tried playing with the field properties, too). Mostly, I just lack/do not know of the tools used in this kind of problem. Any help very much appreciated!

Open problems in Birational Geometry, after BCHM

Rencently a breakthrough was made in the context of the Minimal Model Program by the work of Birkar-Cascini-Hacon-McKernan. They proved that the canonical ring of a smooth or mildly singular projective algebraic variety is finitely generated. Since I'm a master student and so I have no a wide view of the subject (I'm not an expert), I would like to know what are the main open problems in this direction (I mean, in the framework of the Mori Program). More generally, right now what are the driving forces, the big open questions in birational geometry? Feel free to close this question, if too generic for the purposes of the site. Thanks in advance.

Borsuk pairs of Banach spaces

Given X, Y two real Banach spaces, let's say that $(X,\ Y)$ is a Borsuk pair if for any continuous mapping T : {x $\in$ X ; $||x||\leq1$} $\rightarrow$ Y s.t. T is odd on {x $\in$ X ; $||x||=1$}, it follows that the set T^{-1}({ 0 }) is nonempty. My conjecture is : $(X,\ Y)$ Borsuk pair $\Longleftrightarrow$ dim Y < ∞ and dim Y $\leq$ dim X. [Here "dim" stands for the algebraic dimension; it may be a natural number or ∞.] In other words, there is no Borsuk pair with X, Y both infinite-dimensional. Any thoughts ? [There exist several infinite-dimensional versions of the Classical Borsuk Theorem, e.g., when X is reflexive, Y is its dual, and T is a demicontinuous mapping of monotone type.] [I think the "big" problem (if it truly exists, of course ;-)) would be when both X, Y are infinite dimensional, and the density character dens(X) $\gg$ dens(Y), i.e., when X is "huge".]

Center of mass from the abstract point of view, or could the ancient Greeks invent modern analysis?

This is a very open-ended question, which may or may not have a perfect answer, and for which I have a few ideas but nothing like a clear picture. However, I guess it won't hurt to ask to see if people think about such things at all and if they do, what their ideas are. I don't know whether to make it CW or not: on one hand, it is pure mathematics, so we are within the usual set of standards to judge what's right and what's wrong, on the other hand, it is certainly not "a question of the type MO was designed for". So, I'm hesitant to check the community wiki option myself but have absolutely nothing against someone else doing so. I assume that the ancient Greeks had an idea of a complete normed space ($\mathbb R$ and $\mathbb R^2$ would be enough for our purposes for quite a while), a set, a linear transformation, and the center of mass. On the top of it, I assume they had as much common sense (probably more), as we have nowadays. The task is the usual one for Archimedes: given a reasonable non-empty set E in a complete linear space V, assign a point $C(E)$ to it that you can confidently call "the center of mass". For the purposes of this thread, let's consider bounded at most countable subsets in $V=\mathbb R$ first. If we can figure out what to do with this case to everyone's satisfaction, we can move to the next stage. It may be not a really illuminating model, but it has a few quite funny features already. The axioms of the center of mass are just the common sense ones: 1) The center of mass is never outside the closed convex hull of the set. 2) If A, B are disjoint, then $C(A\cup B)\in[C(A),C(B)]$. 3) If T is an affine transformation, then $C(TE)=TC(E)$. 4) (this is a bit tough, so feel free to drop or to modify it if it helps) If A,B are such that the sets $a+B$, $a\in A$ are disjoint, then $C(A+B)=C(A)+C(B)$ I don't know if we really need anything else (in particular, I'm not sure if the addition of the "obvious" definition of the center of mass of a finite set is needed, helpful, or hurtful), but feel free to play with this list in any reasonably way you want. The questions are the usual ones: A) Existence B) Uniqueness C) Way to find $C(E)$ given E. Any ideas, constructions, counterexamples, references, etc. (not necessarily restricted to the model I described) are welcome :). Edit: Thanks to everyone who responded! Let me clarify one thing. Yes, if we can create a meaningful notion of mass (say, if there exists a translation invariant Borel measure that is finite and positive on E), we can define the center of mass in the usual way and the only question will be if the definition is unambiguous. However, if I give you a symmetric set, you'll not hesitate to say that the center of symmetry is also the center of mass. Also, if I give you an infinite set and add one point to it, you'll probably (but not necessarily) agree that the center of mass won't feel this addition, the reason being that the set was infinitely times more massive than the point we added not as mush because we can measure the actual mass in some way but merely because infinitely many disjoint shifts of the point fit inside the set. In other words, quite often we can determine the relative size without being able to assign any meaning to the absolute size. This is one of the loopholes in the integration theory I'd like to exploit and see how far one can get with it. In a sense, that is a straight extension of the original Eudoxus line of thinking, which is why "ancient Greeks" entered the title of the question.

Open problems in the theory of compact quantum groups

What are the important open problems in the theory of compact quantum groups? Or conjectures? Here is an example from An De Rijdt's Ph.D. thesis: Is every compact quantum group with the fusion rules of $SO(3)$ of the the form $A_{aut}(B,\varphi)$ for a finite dimensional C^*-algebra B and a δ-form φ on B? See page 83 at the end of Chapter 3 in An De Rijdt's Ph.D. thesis, available online from https://perswww.kuleuven.be/~u0018768/students/derijdt-phd-thesis.pdf

Randomly switching street lights, in a square city

This is a combinatorics-probability question, best stated however in "recreational" terms. Imagine a $N\times N$ city, meaning that we have N horizontal streets, and N vertical streets. At each crossroads there is a street light. When evening comes, some of the lights are switched on, namely those corresponding to a certain given subset $E\subset(1,\ldots,N)\times(1,\ldots,N)$. Now assume that $2N$ kids come at night and start randomly playing with the switches: there is one such on/off switch at the end of each of the $2N$ streets. Problem: for each of the 4^N overall choices for the various switches, we count the number K of street lights that are switched on. What is the law of this random variable K, as a probability measure on $(1,2,\ldots,N^2)$, depending on the initial set E? [Edit, Jan 20. As signaled by Joseph O'Rourke in his answer below, computing the upper edge of the support of the measure μ_E in my problem is known as the Gale-Berlekamp game, a difficult question (details can be found via Google search). So I realise that my problem is probably extremely difficult, adding the "open-problem" tag. I'd be interested however in the case where E is an Hadamard matrix, cf. discussion with Gerhard Paseman in the comments below. Is there anything known about this measure μ_E? (I mean, not only about its support.) Btw here is the only non-trivial complete computation that I have so far: concerns the case $N=4$, where there are exactly $|E|=4$ street lights, positioned on

the main diagonal of the city. Here $\mu_E=\frac{1}{32}(\delta_4+12\delta_6+6\delta_8+12\delta_{10}+\delta_{12})$. Plus an experimental remark, that I'm not able to prove abstractly: the support of μ_E seems always to be an arithmetic progression.]

How many values a polynomial map misses?

Let F be a field. For a uni-variate polynomial $f(x)$ over F,let $M_f(F)$ denote the number of values that f misses, that is, the cardinality of the subset $F - f(F)$ in F. Assume that f is not surjective, that is, $M_f(F) > 0$. Is the number $M_f(F)$ big? If $F = {\mathbb F}_q$ is a finite field of q elements and $f\in \mathbb{F}_q[x]$ is a polynomial of degree $d>0$, then a simple result shows that if $M_f(F_q) > 0$, then $$M_f(F_q) \geq \frac{q-1}{d}. $$ As q goes to infinity, this lower bound goes to infinity. This suggests the following question for which I do not know the answer. Question. Assume that F is an infinite field. If $M_f(F)>0$. Is it true that $M_f(F) = \infty$? In other words, for an infinite field F, if $f \in F[x]$ misses one value, is it true that f misses infinitely many values? The answer is positive if F is big in the sense that F is algebraically closed (${\mathbb C}$ etc), or topologically closed ($\mathbb{R}$ or $\mathbb{Q}_p$ etc) or if F is a small field such as a Hilbertian field (number fields etc). Anyone has more examples or counter-examples? Gjergji-Zaimi points out that the above question has been asked before, see Can a non-surjective polynomial map from an infinite field to itself miss only finitely many points? To make my question somewhat newer, I will ask a multi-variable version of the question. It is unknown to me even in the case that the field is the complex numbers. Question: Assume that $f=(f_1,..., f_n): F^n -> F^n$ is a FINITE polynomial map in n variables over an infinite field F. If f misses one value, is it true that f misses infinitely many values? I do not know the answer even in the case when $F={\mathbb C}$ is the complex numbers if $n \geq 2$. Note that the finiteness assumption of the map f cannot be dropped, as Kharlamov (2012) has given the example $$f=(u(uv-1), u^2-(uv-1)^2)$$ which misses precisely one point, the origin (0,0) of ${\mathbb C}^2$.

An open problem on general topology

There is an open problem in this paper: Classes defined by stars and neighbourhood assignments by van Mill and others. Problem 4.8. Is a regular (Tychonoff) star compact space metrizable if it has a G_δ-diagonal? A topological space X is said to be star compact if whenever $\mathscr{U}$ is an open cover of X, there is a compact subspace K of X such that $X = \operatorname{St}(K,\mathscr{U})$. More on star compactness see here. My question is this: Is always the cardinality of such regular (Tychonoff) star compact space less than 2^{ω_0}? See the related link here.

Is there any o-minimal expansion of the real field with functions of growth higher than exponential?

Let $\bar{\mathbb{R}}$ be the structure of the real field, that is $(\mathbb{R},0,1,+,-,*,<)$. We say that a function f is of growth higher than exponential if for all $N\in \mathbb{N}$ there $f(x)$ is ultimately greater than $\exp^N(x)$. That is there is we can find $r\in \mathbb{R}$ such that for all $x>k$ we have $\exp^N(x) < f(x)$ where $\exp^N(x)$ stands for $\exp(\exp(\cdots \exp(x)\cdots))$ N times. Is it possible to find an o-minimal expansion (in the model theoretic sense) of $\bar{\mathbb{R}}$ where an f as above is definable?

Topologically distinct Calabi-Yau threefolds

In dimensions 1 and 2 there is only one, respectively 2, compact Kaehler manifolds with zero first Chern class, up to diffeomorphism. However, it is an open problem whether or not the number of topological types of such manifolds of dimension 3 (Calabi-Yau threefolds) is bounded. I would like to ask what is known in this direction. In particular, is it known that the Euler characteristic or the total Betti number of Calabi-Yau threefolds can't be arbitrarily large? Are there any mathematical (or physical?) reasons to expect either answer? As a side question: I remember having heard several times something like "Calabi-Yau 3-folds parametrize (some kind of) vacua in string theory" but was never able to make precise sense of this. So any comments on this point or references accessible to mathematicians would be very welcome.

Status of Grothendieck's conjecture on homomorphisms of abelian schemes

In [1] Grothendieck posits the following: Conjecture. Let S be a reduced connected scheme, locally of finite type over Spec($\mathbf{Z}$) or a field k, A and B two abelian schemes over S, l a prime number, $u_l: T_l(A) \rightarrow T_l(B)$ a homomorphism, and suppose that there exists a point $s\in S$ such that u_{ls} comes from a homormophism $u_s: A_s \rightarrow B_s$ of abelian schemes over $k(s)$. Then there exists an integer $n>0$ and a homomorphism $v: A \rightarrow B$ such that $T_l(v)=n u_l$. Next Grothendieck remarks that the conjecture follows from Tate's conjectures on algebraic cycles. He then proceeds to a give a proof, using the Serre-Tate theorem, for the case of a characteristic zero base field for which the statement holds with $n=1$. Question: What is the current status of this conjecture? If not resolved, are there any partial results for the positive characteristic case? Here is what I've spotted in the literature so far, all characteristic zero: Deligne in the second of three papers on Hodge theory, proves results about homomorphisms of abelian schemes over schemes S of finite type over $\mathbf{C}$. For instance: Proposition (Deligne 4.4.12 [2]) : Let $f: X \rightarrow S$ be an abelian scheme over a smooth scheme S. The following conditions are equivalent: (i) For every abelian scheme $g: Y \rightarrow S$, we have $$ \mathrm{Hom}_S(X,Y) \cong \mathrm{Hom}_S(R_1 f_* \mathbf{Z}, R_1 g_* \mathbf{Z}) $$ (ii) The condition (i) is verified for $X=Y$, and the centre Z of $\mathrm{End}_S(X)\otimes \mathbf{Q}$ does not admit a complex place $\rho: Z \rightarrow \mathbf{C}$ such that the direct factor $R_1 f_*\mathbf{Q} \otimes_{Z,\rho} \mathbf{C}$ of $R_1 f_* \mathbf{C}$ is of pure Hodge type (-1,0). Along similar lines, S.G. Tankeev in a 1976 paper [3] proves if S is a connected smooth curve over $\mathbf{C}$, and $\pi_i: X_i \rightarrow S, i=1,2$ are two abelian schemes, then under some natural conditions, the canonical homomorphism $$ \mathrm{Hom}_S(X_1,X_2) \rightarrow \mathrm{Hom}(R_1 \pi_{1*} \mathbf{Z}, R_1 \pi_{2*} \mathbf{Z})$$ is an isomorphism. In a paper the following year [4] Tankeev proves a Tate module variant of the above, of the form $$ \mathrm{Hom}_k(I_1,I_2)\otimes_\mathbf{Z} \mathbf{Z}_l \cong \mathrm{Hom}_G(T_l(I_1), T_l(I_2)),$$ where $G=\mathrm{Gal}(\overline{k}/k)$, and I_1, I_2 are abelian varieties over $k(t)$ whose Néron models admit compactifications with certain properties. Are there other well-known results along the same lines? I would especially like to know about the characteristic p case, as well any results that actually spread a homomorphism of abelian varities over a point of S to maps of abelian schemes over S, as in the conjecture. [1] A. Grothendieck Un théorème sur les homomorphismes de schémas abéliens Invent. Math. 2 59-78 (1966) [2] P. Open problems in PDEs, dynamical systems, mathematical physics

(This question might not be appropriate for this site. If so, I apologize in advance. I would have posted to mathstack, but I'm looking for advice from active researchers.) I am an undergrad in math and physics getting ready to apply to grad school. So far, I know that I enjoy PDEs (and most kinds of analysis, generally), mathematical physics, and especially dynamical systems. But this is way too broad for choosing a Ph.D. program. My background in these subjects is somewhere between the undergraduate and graduate level, but certainly not 'up to date' or research-level. I want to get a clearer picture of these fields as they exist today. If I'm going to try to contribute to these topics in the next 5-10 years, I'd like to know what I'll be getting into. If you work in these fields, or you have colleagues who do, how would you describe the current state of affairs? Specifically: What are people trying to accomplish? How do those things fit into a larger picture? What are the obstructions? What are some of the major recent advances? What would you like to see happen over the next few decades? I'm looking for technical descriptions, preferably with references to actual papers. Pretend you were describing your work to a fellow mathematician from an entirely different specialty. Don't worry if it's over my head (I'm sure it will be); the point is to get a taste, to help narrow my interests, and to have a guide to come back to over the years. Thanks!

Surfaces filled densely by a geodesic

Which smooth, closed surfaces $S \subset \mathbb{R}^3$ have no single geodesic γ that fills S densely? Say a geodesic γ "fills S densely" if the closure of the set of points through which γ passes equals S. Some examples: A sphere: every geodesic is a great circle. Zoll surfaces, as discussed here: "Surfaces all of whose geodesics are both closed and simple." An ellipsoid. (Image from GeographicLib.) A torus generally has many geodesics that fill the surface. (Image by John Oprea) My assumption is that almost all surfaces have geodesics that fill them. Is this known, under any interpretation

of "almost all"? I would also be interested in extending the list of exceptional surfaces beyond {sphere, Zoll, ellipsoid}. Thanks for pointers! Answers Summary (18Apr2013): (Robert Bryant, Mikhail Katz) Any surface of revolution with poles has no dense geodesic. This holds for convex or nonconvex surfaces of revolution. (Robert Bryant) There are generalizations of Liouville surfaces (due to Goryachev-Chaplygin and to Dullin-Matveev) that have no dense geodesic. (Misha Kapovich) Every surface may be perturbed by gluing on "focusing caps" so that it has dense geodesics. (Keith Burns) Guess: There is always a dense geodesic on a closed Riemannian surface of genus ≥ 2.

Deligne-Simpson problem in the symmetric group

Question. Let $C_1,\dots,C_k$ be conjugacy classes in the symmetric group S_n. (More explicitly, each C_i is given by a partition of n; C_i consists of permutations whose cycles have the length prescribed by the partition.) Give a necessary and sufficient condition on C_i that would ensure that there are permutations $\sigma_i\in C_i$ with $$\prod\sigma_i=1.$$ Variant. Same question, but now σ_i's are required to be irreducible in the sense that they have no common invariant proper subsets $S\subset\lbrace 1,\dots,n\rbrace$. I am not certain how hard this question is, and I would appreciate any comments or observations. (I was unable to find references, but perhaps I wasn't looking for the right things.) This question is inspired by Jonah Sinick's question via the simple Geometric interpretation. Consider the Riemann sphere with k-punctures $X=\mathbb{CP}^1-\lbrace x_1,\dots,x_k\rbrace$. Its fundamental group $\pi_1(X)$ is generated by loops γ_i ($i=1,\dots,k$) subject to the relation $$\prod\gamma_i=1.$$ Thus, homomorphisms $\pi_1(X)\to S_n$ describe degree n covers of X, and the problem can be stated as follows: Determine whether there exists a cover of X with prescribed ramification over each x_i. The variant requires in addition the cover to be irreducible. Background. The Deligne-Simpson Problem refers to the following question: Fix conjugacy classes $C_1,\dots,C_k\in\mathrm{GL}(n,\mathbb{C})$ (given explicitly by k Jordan forms). What is the necessary and sufficient condition for existence of matrices $A_i\in C_i$ with $$\prod A_i=1$$ (variant: require that A_i's have no common proper invariant subspaces)? There are quite a few papers on the subject; my favorite is Simpson's paper, which has references to other relevant papers. The problem has a very non-trivial solution (even stating the answer is not easy): first there is a certain descent procedure (Katz's middle convolution algorithm) and then the answer is constructed directly (as far as I understand, there are two answers: Crawley-Boevey's argument with parabolic bundles, and Simpson's construction using non-abelian Hodge theory). The same geometric interpretation shows that the usual Deligne-Simpson problem is about finding local systems (variant: irreducible local systems) on X with prescribed local monodromy. So: any remarks on what happens if we go from $\mathrm{GL}(n)$ to S_n?

A conjecture on closed discrete subset

I am struggling with this old problem, which is also posted here: Let X satisfy countable chain condition(abbreviated as CCC) and X has a regular G_δ-diagonal. Then the cardinality of X is at most $\mathfrak c$. X has a regular G_δ-diagonal iff there is a collection of open sets of X^2, say $\lbrace U_n: n\in N\rbrace$, such that $\Delta=\bigcap\lbrace \overline{U_n}: n \in N\rbrace$, where $\Delta=\lbrace(x,x): x \in X\rbrace$. Note that the question is answered; however I hope to get new proof. By certain effort, If $|X|>\mathfrak c$, we can get an uncountable closed discrete subset S of X, and for any point $x \in X$, there exists an open set U_x such that $\overline{U_x} \cap S$ has at most one point. I would like to know whether the following conjecture is right, wrong, or neither: Let X be a Hausdorff space. If $S \subset X$ is an uncountable closed discrete subset of X, and for any point $x \in X$, there exists an open set U_x such that $\overline{U_x} \cap S$ has at most one point. Then could we obtain an uncountale collection of disjoint open sets in X? Thanks for your any help.

Optimal inspection path on a sphere

Suppose you would like to "inspect" every point of a unit-radius sphere $S \subset \mathbb{R}^3$ by walking along a path γ on S, but you can only see a distance d from where you stand. Q1. For a given $d \in (0,\pi]$, what are the shortest such paths $\gamma(d)$? Two other ways to define $\gamma(d)$: The shortest path γ such that every point on S is no more than a distance d from some point of γ. The shortest path γ such that the union of disks of radius d centered on every point of γ cover S. For $d \in [\pi/2,\pi]$, $\gamma(d)$ is an arc of a great circle of length $2\pi - 2d$. So, for $d=\pi$, γ is a single point; for $d=3\pi/4$, γ is an arc of length $\pi/2$; for $d=\pi/2$, γ is a semicircle. As d approaches zero, it might be that γ is a type of spiral, e.g.: (Image from grabcad.com.) What is quite unclear to me is when d is less than but close to $\pi/2$. For example, suppose $d = \frac{5}{12}\pi = 75^\circ$. The union of disks of this radius centered on the equatorial semicircle that works for $\pi/2$ is shown in (a) below: a strip connecting the north and south poles is uncovered (blue circles are boundaries of disks of radius d centered on γ): One can construct a candidate γ as in (b) above: extend the semicircle at each end so that all points on the equator are reached, and add short vertical sections, red to reach the north pole, and green to reach the south pole. It does not seem likely that such sharp turns yield the shortest γ. Perhaps this question can be answered even without precise understanding of $\gamma(d)$ for all d: Q2. Does $\gamma(d)$ vary continuously with respect to d? I originally wanted to explore this for any (smooth, closed, compact) surface in $\mathbb{R}^3$, but it already seems not so straightforward for the sphere. Q3. Has this question been studied before? It feels classical. The question could also be posed for $(d{-}1)$-dimensional spheres in $\mathbb{R}^d$, again seeking an optimal inspection path for each d. (My interest in $\mathbb{R}^3$ stems from two related

concepts: Voronoi diagrams on a surface, and the cut locus with respect to a path, although neither seems to help here.) Thanks for any pointers or ideas! 9Aug2022. This issue was touched again by Fejes Tóth's Exploring a planet problem by Zhao, Yufei. "Exploring a planet, revisited." American Mathematical Monthly (2022): 1-3. But the Tóth version uses n great-circle satellites. Related to the Shortest closed curve to inspect a sphere, but quite distinct. As far as I know, my original questions remain unsolved. (Related earlier MO questions: Optimal paintbrush geodesics; Shortest closed curve to inspect a sphere.)

How closed-form conjectures are made?

Recently I posted a conjecture at Math.SE: $$\int_0^\infty\ln\frac{J_\mu(x)^2+Y_\mu(x)^2}{J_\nu(x)^2+Y_\nu(x)^2}\mathrm dx\stackrel{?}{=}\frac{\pi}{2}(\mu^2-\nu^2),$$ where $J_\mu(x)$ and $Y_\mu(x)$ are the Bessel function of the first and second kind. It is supported by numerical calculation with hundreds of digits of precision for many different values of μ, ν. The question is open for several days with +500 bounty on it and is not resolved yet. But my question here is not about if this conjecture true or false. Obviously, several possible closed forms matched my numeric calculations, for example: $$\left(\frac{\pi}{2}+7^{-7^{7^{7^{7^{7^{\sqrt{5}+\sin \mu\nu}}}}}}\right)(\mu^2-\nu^2).$$ But for some reason that I cannot clearly explain (or even understand) I selected the simpler one, and I am strongly inclined to search for its proof rather than a disproof. I believe most people would feel and behave exactly the same way. (1) Are there any mathematical or philosophical reasons supporting this position? Why when we calculate some sum or integral (which do not contain explicit tiny quantities like $10^{-10^{10^{.^{.^{10}}}}}$) with thousands of digits of precision and it matches some simple closed-form expression, we inclined to believe this is the exact equality rather than an accidental very close value? (2) Are there known cases when such intuition turned out to be wrong? And one more question: (3) Do you believe there can be exact closed forms for some infinite sums or integrals, that cannot be proved in ZFC or any its reasonable extension (like adding some large cardinal axioms) - so to speak, equalities that hold without any reason.

A conjecture on intersection of some intervals.

It was proved here that if $a\in \mathbb{N}_{\geq3}$ then $$\bigcap_{i = 1}^{a} \bigcup_{j = 0}^{i-1} \left[\frac{1+aj}{i},\frac{a(j+1)-1}{i}\right] = \varnothing \tag{1}$$ It may be conjectured that forcing $i\ne b$, where $1\leq b< a$, renders (1) untrue, that is, the result is not an empty interval. We look at the diagram here from the link above for $a=5$ to get a better picture: Red is the interval, Yellow are the gaps between the intervals that cause the intersection to be a null set, white gaps do not effect the intersection. The conjecture here says that if we were to remove any one of the top 4 strips, then there will form a region of intersection. I tried analyzing the gaps but everything seems to meet up at a dead end. What tools may one employ to handle such problems?

Distinctive property of the primes 17 and 19?

Consider the question whether it is true that a prime number p divides $1^1+2^2+3^3+....+(p-1)^{p-1}$ if and only if $p \in \{17,19\}$. For the obvious heuristic reasons, for large n one would expect there to be roughly $\ln(\ln(n))$ such primes $p < n$, however it seems that presently no examples other than 17 and 19 are known. Is there a more efficient way of looking for examples than the brute force method of testing the primes one-by-one?

Needle probing for a convex body

Suppose there is an unknown closed convex body K of volume vol$(K) = V$ inside the unit cube $[-\frac{1}{2}, \frac{1}{2}]^d$ in $\mathbb{R}^d$. You are permitted to probe with a (one-dimensional) ray r, which detects whether r includes some point of K, or instead if $r \cap K = \varnothing$. My question is: Q1. What is the fewest number of such needle probe rays that guarantee hitting K, as a function of its volume V? I am especially interested in $\mathbb{R}^3$. For example, for $V \ge \frac{1}{2}$, one ray through the origin parallel to an axis suffices. Here such a ray touches the boundary of a body K with vol$(K)=\frac{1}{2}$: To be specific: Q2. How many needle probes suffice for $V \ge \frac{1}{4}$ in $\mathbb{R}^3$? Four parallel rays in a grid pattern do not suffice, but nine do suffice (I believe): Q3. In $\mathbb{R}^3$, is it sometimes more efficient to use nonparallel rays? This feels like a classic problem, but I am not finding literature. Thanks for pointers or ideas! Update 1 (28May13). Here is Yoav Kallus' example showing that dropping the middle of the 9 points of the grid permits a triangle with area larger than $\frac{1}{4}$ to avoid detection: Update 2 (30May13). Q2 and Q3 are now answered by Benjamin Dickman and Douglas Zare: for $V=\frac{1}{4}$, three needles suffice, and more are needed for parallel needles. Q1, in its full generality, is difficult, and so I've added the "open problem" tag.

An elementary expression for $_3F_2(1,1,9/4;2,2;-1)$

Consider the following series: $$S=\sum_{n=1}^\infty\frac{(-1)^n\ \Gamma\left(\frac{5}{4}+n\right)}{n^2\ \Gamma(n)}.$$ It can be expressed in terms of a hypergeometric function: $$S=-\frac{5}{16}\Gamma\left(\frac{1}{4}\right)\ { _3F_2}\left(1,1,\frac{9}{4};2,2;-1\right).$$ I tried to find an expression of S using elementary functions and ended up with this conjecture: $$S\stackrel{?}{=}\frac{\Gamma\left(\frac{1}{4}\right)}{16}\Bigg(8\sqrt[4]{8}-16-\ln\frac{24\sqrt{69708+49291\sqrt{2}}+3168\sqrt{2}+4481}{4096}\\\\+\arctan\frac{24\sqrt{49291\sqrt{2}-13260}}{6913}\Bigg).$$My derivation of this formula is quite long and uses a non-rigorous, heuristic approach involving heavy use of techniques like guessing sequence formulas using Mathematica command FindSequenceFunction and OEIS superseeker, and recognizing approximate numeric quantities using RootApproximant, TranscendentalRecognize, Inverse Symbolic Calculator and Mathematica command WolframAlpha[ToString[value], IncludePods -> "PossibleClosedForm", TimeConstraint -> ∞] The formula holds with at least 1800 decimal digits of precision. Now I am looking for a rigorous way to prove this formula. Can you suggest any ideas how to do that?

Does this modified Hasse principle hold for curves?

Let C be a curve over $\mathbb Q$ with a point P on Pic^1. For each $\mathbb Q$-rational point Q, $Q-P$ is a point on the Jacobian J. We can use the map $H^0(\mathbb Q, J) \to H^1(\mathbb Q,J[n])$ to obtain a class in $H^1(\mathbb Q,J[n])$ associated to each rational point. Rather than trying to find a local obstruction to existence of rational points on C, we could try to find a local obstruction to existence of rational points in each $H^1(\mathbb Q, J[n])$ class. A local obstruction at $\mathbb Q_p$ would occur when the class, projected down to $H^1(\mathbb Q_p, J[n])$ does not arise from any $\mathbb Q_p$-rational point of C. If C does not have rational points, must there be some n such that each class in $H^1(\mathbb Q, J[n])$ has a local obstruction at some p or at ∞?

Finite Rank Commutators

My former student Detelin Dosev and I are interested in classifying the commutators in $L(X)$, the bounded linear operators on the Banach space X (see our joint paper on my home page or the ArXiv and the references therein, and recall that T is a commutator means that there are A and B in $L(X)$ so that $T=AB-BA$). If T is a finite rank operator in $L(X)$ with zero trace then it is classical that T is a commutator. The converse is obviously true when X is finite dimensional. Conjecture. There is an infinite dimensional Banach space X such that all finite rank commutators in $L(X)$ have zero trace. If true, this conjecture is very hard to prove, but maybe it is known to be false? We are also interested in conditions on X that guarantee that all finite rank operators in $L(X)$ are commutators. If X is isomorphic (meaning linearly homeomorphic) to its closed subspaces of codimension one, then rank one projections in $L(X)$ are commutators and hence every finite rank operator in $L(X)$ is the sum of two commutators, but we do not know whether every finite rank operator in $L(X)$ is a commutator. If also X contains a complemented subspace isomorphic to $X \oplus X$, then every diagonalizable finite rank operator in $L(X)$ is a commutator, but we still don't know whether all finite rank operators in $L(X)$ are commutators. Are we missing something easy? A Banach space X is said to have a Pelczynski decomposition provided X is isomorphic to $(X \oplus X \oplus X \oplus ...)_p$ for some $1 \le p \le \infty$ or $p = 0$. A general result is that if X admits a Pelczynski decomposition, then every compact operator on X is a commutator, so standard spaces do not give examples of finite rank non commutators.

Hilbert subspaces of indefinite inner product spaces

Let E be a real linear space, endowed with a non-degenerate symmetric bilinear form $(.,.)$. Suppose that the [indefinite] inner product space $(E,(.,.))$ satisfies the following [sequential] properties: (WSC) If the sequence { ${(x_{n},\ y)}$ } is Cauchy for each y in E, then there exists some x in E such that $\left(x_{n}-x,y\right)$ $\rightarrow$ 0 whenever y in E. (That is to say, $(E,(.,.))$ is weakly sequentially complete.) and (DPG) If $\left(x_{n},y\right)$ $\rightarrow$ 0 for every y in E, then $\left(x_{n},x_{n}\right)$ $\rightarrow$ 0. (That would be sort of "Dunford-Pettis & Grothendieck'' property for indefinite inner product spaces.) Suppose also that $|E|$ is "big enough'' (at least $|E|$ $>|\mathbb{R}|$). Conjecture. $(E,(.,.))$ contains an infinite-dimensional Hilbert subspace. (That is, there exists a linear isometry from $(\ell^{2},<.,.>)$ into $(E,(.,.))$.)

Prime divisors of numbers 2^n + 3

I'm interested in the following problem: do there exist infinitely many prime numbers p such that $p^2|2^{n}+3$ for some natural number n? Some motivation: If we replace the function $2^n + 3$ with the $f(n)$ where $f \in \mathbb{Z}[x]$ is non-constant that this is true (follows Hensel lemma). So, it's rather natural to try proving this for some other non-polynomial functions. $2^n + 3$ is an easy example of such function. There is also another good reason: sequence $a_n = 2^{n} + 3$ satisfies the reccurence relation: $a_{n+2} = 3a_{n+1} - 2a_{n}$. And for example this problem is true for Fibonacci sequence. So, for Fibonacci it's easier even if the closed form of Fibonacci numbers is more complicated. But I think that the reason of this is that the Fibonacci numbers satisfy some "good" identities which other sequences don't have to share. Now some remarks: It's easy

exercise to prove that there are infinitely many primes p such that $p|2^{n}+3$. Also, if we try "correcting" n to work also for p^2 and we try $m=n+k(p-1)$ we see that it is possible unless p is Wieferich prime, i.e. satisfies $p^2|2^{p-1}-1$. And this gives us nothing as we don't know much about Wieferich primes... This method can of course be generalized in such way: if $p|2^{n}+3$ and order of 2 mod p^2 is greater than order of 2 mod p then we can find m such that $p^2|2^{m}+3$. But I don't really think that it helps. I'm interested in some information about this problem (especially if it's open or not) and also related problems. We can ask a general question: for which functions f we know that this is true? Edit: Sorry for the confusion with k, deleted.

Open problems in algebraic topology and homotopy theory

Some time ago (I see it was initially written before 1999?) Mark Hovey assembled a list of open problems in algebraic topology. The list can be found here. Some of the problems I know about have been worked on quite a bit since the time of writing. The list is very good as is, but there must also be a few good additions since 1999. Can someone point me to a more recent list of open problems in algebraic topology? My googling isn't turning up much else. Thank you!

A question about the Axiom of Choice

Let AC denote the Axiom of Choice. Let PP denote the so-called "Partition Principle" which states that "If S is a non-empty set and T is a non-empty set of pairwise disjoint subsets of S, then S can be mapped onto T". It is well known that "AC implies PP" is provable in ZF, but the question of whether "PP implies AC" is provable in ZF has long been an open problem. What is the present status of this problem? Has any progress been made on it? Or-on the other hand-have any models of ZF been constructed in which pp is true and some consequence of AC -such as the existence of non-measurable sets of real numbers-is false? If "pp implies AC" could be proved in ZF, this would seem to provide a powerful philosophical argument for accepting AC. In my opinion, any set theory in which pp can be disproved yields a really counter-intuitive picture of the "Set-theoretical Universe".

Set-theoretic reformulation of the invariant subspace problem

The invariant subspace problem (ISP) for Hilbert spaces asks whether every bounded linear operator A on l^2 (with complex scalars) must have a closed invariant subspace other than $\{0\}$ and l^2. A subspace E is invariant for A if $A(E) \subseteq E$. Some time ago I noticed a reformulation that has a set-theoretic flavor. Let P be the set of all linear operators A from a finite-dimensional subspace of l^2 into l^2 such that (1) $\|A\| < 1$ and (2) if E is a nonzero subspace of the domain of A then $A(E) \not\subseteq E$. Order P by reverse inclusion and for any unit vectors $v,w \in l^2$ define $$D_{v,w} = \{A \in P: \langle A^nv,w\rangle \neq 0\mbox{ for some n such that A^nv is defined}\}.$$ It is easy to see that each $D_{v,w}$ is dense in P. Having a counterexample to the ISP is the same as having a filter of P that meets each $D_{v,w}$. My question for the set theory experts on MO is simply whether this version of the problem suggests any possible approaches?

Small quadrilaterals containing a given convex region

It is easy to prove that (*) Every convex planar set of area 1 is contained in a quadrilateral of area 2. It is also easy to see that statement (*) remains true if the constant 2 is replaced with a somewhat smaller one. Contest: Find such a constant, the smaller the better. Update: Reaching $\sqrt 2$ and even a strictly smaller value was proved by Chakerian (1973) and Kuperberg (1983) and the research challenge offered is to improve it even further, and perhaps even to verify the conjecture that the minimum is attained by a regular pentagon. But any nice arguments for bounds below 2 are welcome.

Integer-distance sets

Let S be a set of points in $\mathbb{R}^d$; I am especially interested in $d=2$. Say that S is an integer-distance set if every pair of points in S is separated by an integer Euclidean distance. What are examples of maximal integer distance sets? (Maximal: no point can be added while retaining the integer-distance property between all pairs.) Of course the lattice points along any one line parallel to a coordinate axis in $\mathbb{R}^d$ constitute a countably infinite integer-distance set. What is an example of an infinite integer-distance set of noncollinear points? I know that Euler established that every circle contains a dense rational-distance set. Scaling any one circle by a large common denominator provides a rich,

but finite integer-distance set. For example, these five points on a circle are all separated by integer distances: $$ (1221025, 0), (781456, 586092), (439569, 586092), (270400, 507000), (180625, 433500) $$ I'm sure this is all known... Thanks for enlightening me! (This is tangentially related to my earlier question, "Rational points on a sphere in $\mathbb{R}^d$.") Update1. It turns out that determining the integer-distance sets is fundamentally open. What is known is nicely summarized by Robert Israel and "Daniel m3." In particular, via the Kreisel & Kurz paper, it is unknown (or was unknown in 2008) whether or not there exists an 8-point integer-distance set in $\mathbb{R}^2$, with no three of the points collinear and no four cocircular. Update2. Also open is a related problem identified by Nathan Dean: How many non-cocircular integer-distance points can be found on a parabola, a scaling of $y = x^2$? Nathan proved there are infinitely many sets of three such points; Garikai Cambell proved there are infinitely many sets of four such points. But the existence of five such points seems open. I just learned the parabola problem from this MSE question. Update3 (21 Jul 2013). I ran across this just-published paper, which explores the in-some-sense obverse of the question I asked: What are the largest point sets in $\mathbb{R}^d$ that avoid points an integral distance apart. Kurz, Sascha, and Valery Mishkin. "Open Sets Avoiding Integral Distances." Discrete & Computational Geometry (2013): 1-25. (Springer link) Update4 (29 Nov 2014). There is a nice article at Dick Lipton's blog on Ulam's 70-year-old un-resolved conjecture: If S is an rational-distance set, then it is not dense in the plane. And that article cites the Kurz-Mishkin paper above. Update5 (11 Mar 2024). Greenfeld, Rachel, Marina Iliopoulou, and Sarah Peluse. "On integer distance sets." arXiv:2401.10821 abstract (2024). "Our main result is that any integer distance set in the Euclidean plane has all but a very small number of points lying on a single line or circle. From this, we deduce a near-optimal lower bound on the diameter of any non-collinear integer distance set..." "It turns out that all so-far-known integer distance sets ... are of a similar special form: they have all but up to four of their points lying on a single line or circle. In this paper, we develop a new approach to the study of integer distance sets that enables us to prove a structure theorem partially explaining this phenomenon."

Tiling the square with rectangles of small diagonals

For a given integer $k\ge3$, tile the unit square with k rectangles so that the longest of the rectangles' diagonals be as short as possible. Call such a tiling optimal. The solutions are obvious in the easy cases when k is the square of an integer and for a few small values of k only (unpublished). In each of the solved cases, the sides of all rectangles turn out to be rational and their diagonals are equal. Question. In an optimal tiling, must the sides of all rectangles be rational and their diagonals be equal? The analogous question for tiling the n-dimensional cube with rectangular boxes can be asked for every $n\ge3$ as well.

Can six square numbers be simultaneously represented in a single sum of consecutive odd numbers?

I had some free time from my work to do a little exploration regarding the existence (or non existence) of perfect cuboids. A solution is represented by the set of Diophantine equations: $a^2 + b^2 = x^2$ $a^2 + c^2 = y^2$ $b^2 + c^2 = z^2$ $a^2 + b^2 + c^2 = R^2$ If there exists a perfect cuboid, it implies that there is a consecutive sum of odd numbers from 1 to the Rth odd number representing the space diagonal of a perfect cuboid, and that Six other perfect squares representing the face diagonals and edges also exist with the sum. It also means that each edge and face diagonal can be represented as a sum starting from 1 within R^2 I represent this consecutive arithmetic sequence like this: $1+3+5+...+ R_o = R^2$ Where R_o is the Rth odd number in a consecutive sequence. The set of edge, face diagonals and the body diagonals $[a,b,c,x,y,z,R]$ can each be represented similarly. By using the fourth equation in the set, we see that: $(1+3+5+...+a_o) + (1+3+5+...+b_o) + (1+3+5+...+c_o) = 1+3+5+...+R_o$ Then $(1+3+5+...+x_o) + (1+3+5+...+c_o) = 1+3+5+...+R_o$ Since by first equation and our definition, $(1+3+5+...+a_o) + (1+3+5+...+b_o) = (1+3+5+...+x_o)$ Which Implies $1+3+5+...+x_o = (c+1)_o + ... + R_o$ by subtracting $(1+3+5+...+c_o)$ Which implies: $x^2 = (c+1)_o + ... + R_o$ By using the same process, we can derive this for the others: $a^2 = (z+1)_o + ... + R_o$ $b^2 = (y+1)_o + ... + R_o$ $c^2 = (x+1)_o + ... + R_o$ $x^2 = (c+1)_o + ... + R_o$ $y^2 = (b+1)_o + ... + R_o$ $z^2 = (a+1)_o + ... + R_o$ Ultimately, the Perfect Cuboid Problem implies that there are two unique ways to represent each side and face diagonal in two different ways. Another way to see this is that it is possible to represent each side and face diagonal between $1+ ... + R_o$ both forwards and backwards. This also demonstrates that $a<b<c<x<y<z<R$ That is about as far as I got. My efforts now are attempts to demonstrate that it is not possible for one of these to be true, and by extension disproving others. I also believe that by extending the set of Diophantine equations, Perfect "Hypercuboids" can be disproved as well. Suggestions are appreciated.

What are the divisors of $2n^2 - \sigma_{1}(n^2)$ for composite n?

What are the divisors of $2n^2 - \sigma_{1}(n^2)$ for composite n? Here, σ_{1} is the classical sum-of-divisors function. For example, $\sigma_{1}(3^2) = 1 + 3 + {3^2} = 13$. (The function $D(x) = 2x - \sigma_{1}(x)$ is called the deficiency of x [see OEIS Sequence A033879].) Now, for the motivation behind the question: Let $N = {q^k}{n^2}$ be an odd perfect number given in Eulerian form (i.e., q is prime with $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q, n) = 1$). Since N is perfect, we have the equation $$\sigma_{1}(N) = 2N \Longleftrightarrow \sigma_{1}({q^k}{n^2}) = \sigma_{1}(q^k)\sigma_{1}(n^2) = 2{q^k}{n^2}.$$ We can express $\sigma_{1}(q^k)$ as $$\sigma_{1}(q^k) = 1 + q + \ldots + q^{k-1} + q^k = \left(1 + q + \ldots + q^{k-1}\right) + q^k = \sigma_{1}(q^{k-1}) + q^k$$ whereupon we have $$\sigma_{1}(q^k)\sigma_{1}(n^2) = \left(\sigma_{1}(q^{k-1}) + {q^k} \right)\sigma_{1}(n^2) = 2{q^k}{n^2}.$$ Dividing through by q^k in $$\left(\sigma_{1}(q^{k-1}) + {q^k} \right)\sigma_{1}(n^2) = 2{q^k}{n^2},$$ we get $$2n^2 - \sigma_{1}(n^2) = I(q^{k-1})\cdot{\frac{\sigma(n^2)}{q}},$$ where $$I(x) = \frac{\sigma_{1}(x)}{x}$$ is the abundancy index of x. From the last equation, since $q \geq 5$ implies $1 \leq I(q^{k-1}) < \frac{5}{4} = 1.25$, we have the biconditional $$k = 1 \Longleftrightarrow 2n^2 - \sigma_{1}(n^2) = \frac{\sigma(n^2)}{q}.$$ In other words, we have the biconditional $$k = 1 \Longleftrightarrow 2n^2 - \sigma_{1}(n^2) = \frac{\sigma(n^2)}{q^k}.$$ [In the paper The Abundancy Index of Divisors of Odd Perfect Numbers, the assertion $k = 1$ for odd perfect numbers $N = {q^k}{n^2}$ was called as Sorli's conjecture -- although, in a more recent (proceedings) paper by B. Beasley of Presbyterian College, titled Euler and the Ongoing Search for Odd Perfect Numbers, he points out that it was in fact Descartes who initially made this conjecture (in a letter to Marin Mersenne in 1638), "with Frenicle's subsequent observation occurring in 1657".] Now, following Broughan, et. al., it is known that the index $\frac{\sigma_{1}(n^2)}{q^k}$ of the Euler factor q^k satisfies $$\frac{\sigma_{1}(n^2)}{q^k} \geq 315,$$ and $$\frac{\sigma_{1}(n^2)}{q^k}$$ cannot take any of the 11 forms $$\{p, p^2, p^3, p^4, p^5, p^6, {p_1}{p_2}, {p_1}^2{p_2}, {p_1}^3{p_2}, {p_1}^2{p_2}^2, {p_1}{p_2}{p_3}\}$$ where p is any odd prime and p_1, p_2, p_3 are any distinct odd primes. Now back to the original question: We want to know the divisors of $2n^2 - \sigma_{1}(n^2)$ for composite n. Note that, if n is prime, say r, then we have $$2n^2 - \sigma_{1}(n^2) = 2r^2 - \sigma_{1}(r^2) = 2r^2 - (r^2 + r + 1) = r^2 - r - 1 = r(r - 1) - 1,$$ which is, in general, odd (so that $2r^2 - \sigma_{1}(r^2) \equiv 1 \pmod 2$ for r prime.) [In fact, since $\sigma_{1}(n^2) \equiv 1 \pmod 2$ for all positive integers n, then we have $2n^2 - \sigma_{1}(n^2) \equiv 1 \pmod 2$ for all positive integers n.] Of course, the situation is more complicated when $\omega(n) \geq 2$ (where $\omega(x)$ is the number of distinct prime factors of x).

Product of exponents of prime factorization

Let $p(n)$ be the product of the exponents of the prime factorization of n. For example, $$p(5184) = p(2^6 3^4) = 24 \;,$$ $$p(65536) = p(2^{16}) = 16 \;.$$ Define $P(n)$ as the number of iterations of $p(\;)$ to reduce n to 1. For example, $P(5184) = 3$ because $$p(5184)=24, \;p(24) = p(2^3 3^1) = 3, \;p(3)=1 \;;$$ and $P(65536)=4$ because $$p(65536) = 16, \;p(16)=p(2^4)=4, \;p(4)=p(2^2)=2, \; p(2)=1 \;.$$ Finally, define $m(k)$ to be the minimum value of n such that $P(n) = k$. Q1. What is $m(k)$? (I ask this question out of curiosity, not because it is part of a research program. It was previously posed on MSE.) It is easy to see that $m(1)=2$, $m(2)=4$, and $m(3)=16$, the latter because $16=2^{2^2}$. But, thanks to Calvin Lin's insight, $m(4)$ is not a power of 2, but instead is $m(4)=1296= 2^4 3^4$. I do not know the value of $m(5)$. Q2. More specifically: What is $m(5)$? I do know that $m(5) > 2 \times 10^8$. Update. Will Jagy showed that almost certainly $m(5) = 2^9 3^6 5^4 7^3 11^2 =9681819840000 \approx 10^{13}$. As it seems that an explicit expression for $m(k)$ is not in the offing, I will accept his resolution of Q2 and leave Q1 open.

Is $\varliminf_{n \rightarrow +\infty} |n \sin n| = 0$ correct, where n is an integer?

Is it true that $\varliminf_{n \rightarrow +\infty} |n \sin n| = 0$, where n runs over the integers? The existence of the limes inferior follows from Dirichlet's approximation theorem, but the problem is to prove that it is 0.

Euclidean real quadratic fields

It is known that, under GRH, a real quadratic field is Euclidean iff it is a UFD. So, assuming the conjecture of Gauss and GRH, we expect that there are infinitely many Euclidean real quadratic fields. I want to know if there are any approaches in showing that there are infinitely many Euclidean real quadratic fields by explicitly constructing the Euclidean functions. Can we hope for a single (or finitely many) Euclidean function(s) that will do the job or we need infinitely many different Euclidean functions? Can these Euclidean functions be obtained by modifying the norm function? Since very few non-norm Euclidean quadratic fields are known, can we at all hope for showing the infinitude of real UFD quadratic fields by finding infinitely many Euclidean quadratic fields?

Decidability of equality of elementary expressions

In the following definition the term expression is to be understood as a finite tree built from formal symbols without any predefined meaning assigned to them. Define the set $\mathcal{E}$ of elementary expressions as the minimal set such that: the expression i is in $\mathcal{E}$ if $x\in\mathcal{E}$, then the expression $\exp(x)\in\mathcal{E}$, if $x\in\mathcal{E}$, then the expression $\ln(x)\in\mathcal{E}$, if $x,y\in\mathcal{E}$, then the expression $(x\cdot y)\in\mathcal{E}.$ Now we can assign meaning (a numeric value) to expressions in $\mathcal{E}$ as follows: i is the imaginary unit, $\exp(x)$ is the exponent of x, $\ln(x)$ is the principal branch of the natural logarithm of x (unless the value of x is zero), $(x\cdot y)$ is the product of x and y. These rules do not assign a value to an expression if it contains a logarithm of an expression whose value is zero, e.g. $$\ln(\ln((i\cdot(i\cdot(i\cdot i)))))$$ in which case we say that the expression is invalid. Otherwise (if a value is successfully assigned), we say that the expression is valid. Note that expressions in $\mathcal{E}$ can represent all values that can be constructed from integers and elementary functions, e.g. $\sqrt[3]{3+\sqrt2},\ \sin\frac\pi{17},\ \arctan\frac27,\ \pi^e$, etc. Question: Is validity of expressions in $\mathcal{E}$ a decidable problem? In other words, is there an algorithm that, given an expression e in $\mathcal{E}$ as an input, always terminates and gives a correct yes/no answer indicating if the expression e is valid? Equivalent problems could be to check if a given expression is zero, or to check if two given expressions are equal to each other.

A challenging non homogenous fractional inequality

I have posted this question on Stackexchange but it has received no answer so far. It is a challenging generalization of several difficult inequalities, where none of the usual methods used in inequalities seems to work. I would like to know if someone has a deeper insight into what is happening here. Let $n\in\mathbb N$, $\lambda> 1$ and put $k:=\lambda n$ and $c:=\frac{\lambda-\frac 1n}{\lambda-1}=\frac{k-1}{k-n}$. For reals $a_1,...,a_n\ge 0,$ define $ r:=\prod_{i=1}^n a_i^c$. Then prove or disprove $$ {\sum\limits_{i=1}^n\displaystyle\dfrac {1-a_i }{1 - a_i^{\lambda n}}\geqslant \frac {1-r}{1 -r^{\lambda}}}.$$ For $\lambda\in\mathbb N$, we can write this inequality in a "purely reciprocal" form as$$ {\sum\limits_{i=1}^n\displaystyle\dfrac {1}{1 + a_i + \cdots + a_i^{k-1}}\geqslant \frac {1}{1 + r+ \cdots +r^{\lambda-1}}.}$$ The limit case $\lambda\to 1$ yields $\sum\limits_{i=1}^n\displaystyle\dfrac {1}{1 + a_i + \cdots + a_i^{n-1}}\geqslant 1 \qquad\qquad\ \ \text{ if}\ \ \prod a_i\leqslant 1$ $\sum\limits_{i=1}^n\displaystyle{\dfrac {1}{1 + a_i + \cdots + a_i^{n-1}}} \geqslant \prod a_i^\frac{1-n}n \qquad\text{ if}\ \ \prod a_i\geqslant 1$ The most interesting case of this is of course $\prod a_i=1$. I have proven it for this case for all $n\in\mathbb N$ by calculus, generalizing the (corrected) idea given here. Other special cases that have given rise to my general conjecture above: The case $n=2,k=3$ is equivalent to $ {\dfrac{1}{1+a+a^{2}}+\dfrac{1}{1+b+b^{2}}+\dfrac{1}{1+c+c^{2}}\ge 1 }$, i.e. the case $n=3,\lambda\to1$ with condition $abc=1$. The case $n=2,k=4$, i.e. $ { \dfrac{1}{1+a^2+a^4+a^6}+\dfrac{1}{1+b^2+b^4+b^6}\ge\dfrac{1}{1+a^3b^3} }$, is Vasc's "gm_33 lemma" and is already difficult to prove. There are several proofs of this around, all ad-hoc and rather technical. See http://www.artofproblemsolving.com/Forum/viewtopic.php?t=18857 http://www.artofproblemsolving.com/Forum/viewtopic.php?p=1701829#p1701829 The case $n=2,k=6$ has been suggested in one of those threads as a conjecture. The case $n=3,k=6$ could be called "gm_555 Lemma" and has been suggested by myself. This conjecture says: for $a,b,c\geqslant 0$, $ {\sum\dfrac{1}{1+a^3+a^6+a^9+a^{12}+a^{15}}\ge\dfrac{1}{1+a^5b^5c^5}.}$ One of the striking facts of these inequalities is a certain 'asymmetry' w.r.t. the change $a_i\mapsto\dfrac1{a_i}$. I think that it should be possible, at least for $k\in\mathbb N$, to find proofs similar to the case $n=2,k=4$, but certainly not without the help of a computer. Any ideas on how to tackle this?

On Generalizations of Fermat's Conjecture

We know the following facts: (1) For all $1\leq n\leq 2$ the equation $x_{1}^{n}+x_{2}^{n}=x_{3}^{n}$ has a solution in $\mathbb{N}$. (2) For all $3\leq n$ the equation $x_{1}^{n}+x_{2}^{n}=x_{3}^{n}$ has no solution in $\mathbb{N}$. Question: Is the following generalization true? For all $2\leq m$ both of the following statements are true: (1) For all $1\leq n\leq m$ the equation $x_{1}^{n}+...+x_{m}^{n}=x_{m+1}^{n}$ has a solution in $\mathbb{N}$. (2) For all $m+1\leq n$ the equation $x_{1}^{n}+...+x_{m}^{n}=x_{m+1}^{n}$ has no solution in $\mathbb{N}$.

A Hot Betting On HOD

Remark: This question is based on an open question at the end of a paper by Hamkins, Kirmayer, and Perlmutter: "Generalizations of the Kunen Inconistency". HOD as an inner model of ZFC lies between L and V. But its nature shows a wide degree of flexibility between L -like and V-like behaviors up to different problems. One of the problems about any inner model of ZFC is consistency of existence of a non-trivial self elementary embedding. In this direction the following facts are well known: (a) There is no non-trivial elementary embedding from V to V. (b) Existence of a non-trivial elementary embedding from L to L is an acceptable large cardinal axiom. Here the open question is: Question (1): Is the existence of a non-trivial elementary embedding from HOD to HOD an acceptable large cardinal axiom? I usually discuss with my colleagues about it. I believe that HOD in this problem has a L - like behavior and existence of a non-trivial elementary

embedding from HOD to HOD is an acceptable (not too) large cardinal axiom but one of my friends insists that the facts shows there is no such embedding. Finally we bet on it. Here I want to know about any known partial result around the open problem. So: Question (2): Please introduce any known fact related to the possible answer of question (1) and explain that which one of the scenarios (a) or (b) for HOD seems more possible by this fact.

Forcing with c.c.c forcing notions, Cohen reals and Random reals

I think the following question is due to Prikry: Question. Is it consistent that any non-trivial c.c.c forcing notion adds a Cohen real or a Random real? Is the question still open? What partial results are known about this question (with references, please). Remark. I have the following simple observation which might be well-know. Theorem. Souslin hypothesis (SH) hols iff any non-trivial c.c.c forcing notion adds a new real. Proof. One direction is trivial, since a Souslin tree, considered as a forcing notion, is c.c.c and adds no new reals. For the other direction suppose there is a non-trivial c.c.c forcing notion P which adds no new reals. Let $B=R.O(P)$ be the completion of P. B is a c.c.c. complete Boolean algebra which is (ω, ω)-distributive, hence it is in fact $(\omega, \infty)-$distributive, thus it is a Souslin algebra, which implies the existence of a Souslin tree, and hence SH fails. Update. Can anyone say the first place where the above question has appeared?

Any results towards the irrationality of the sum of reciprocals of perfect numbers?

This question is a follow up to my comment to Sum of the reciprocal of perfect numbers. I would like to know which results have been published about the possible irrationality of the sum of reciprocals of perfect numbers. For example, do we know a lower bound for the denominator of this number provided it is rational? Thanks in advance.

Second duals of Grothendieck spaces

The classical example of a Grothendieck space is ℓ_∞. It is also known that its even duals ℓ_∞^{**}, $\ell_\infty^{(4)}$, $\dots$ are Grothendieck spaces. (See, e.g., this note for the proof of the Grothendieck property of these even duals, which uses the fact that these spaces are $C(K)$ spaces for large Stonian K-s.) Is it known, in general, whether the second dual of a Grothendieck space is a Grothendieck space too? Is there a counterexample? Edit (T. Kania). Let me record here for the future reference that this very question was asked by J. Diestel on p. 105 in J. Diestel, "Grothendieck spaces and vector measures", Vector and Operator Valued Measures and Applications, Acad. Press (1973) pp. 97-108.

Automorphisms of the L-function associated to an elliptic $\mathbb{Q}$-curve

$\DeclareMathOperator\Aut{Aut}\newcommand{\alg}{\mathrm{alg}}\newcommand{\an}{\mathrm{an}}$Edited after Noam Elkies' comment: From what I understand (very little actually), there exist elliptic curves defined over some number fields $\mathbb{K}$ Galois over $\mathbb{Q}$ which are isogenous to all their Galois conjugates and such elliptic curves are called $\mathbb{Q}$-curves. Since two elliptic curves are isogenous if and only if they share the same L-function, can one define the automorphism group of the L-function corresponding to such an elliptic $\mathbb{Q}$-curve in such a way that this group is actually isomorphic to $\operatorname{Gal}(\mathbb{K}/\mathbb{Q})$? EDIT November 25th 2013: it seems rather clear that the automorphism group of the isogeny class of the $\mathbb{Q}$-curve E contains $\operatorname{Gal}(\mathbb{K}/\mathbb{Q})$ as a subgroup. As the L-function F of E determines its isogeny class entirely, the automorphism groups of F and of the isogeny class of E should be isomorphic. Therefore it remains to show that such a group doesn't contain any element not arising from $\operatorname{Gal}(\mathbb{K}/\mathbb{Q})$. EDIT December 6th 2013: There may be a way to provide a definite answer to my question. Suppose $g_1, g_2, \cdots g_n$ are elements of the considered automorphism group not arising from $\operatorname{Gal}(\mathbb{K}/\mathbb{Q})$ and let G be the group generated by $\operatorname{Gal}(\mathbb{K}/\mathbb{Q})\cup \{g_{1},\cdots g_{n}\}$. Then, provided G is realizable over $\mathbb{Q}$, there should exist a number field $\mathbb{L}$ containing $\mathbb{K}$ as a proper subfield such that the considered $\mathbb{Q}$-curve is actually defined over $\mathbb{L}$. Edit April 1rst 2015: I copy and paste here the content of a cross-post MSE question which, after getting one up vote, has received one down vote et two votes to close without any explanation even though I did my best to improve it. So here it is: "If I'm not mistaken, the isogeny class of E/K contains an abelian group $Z^{r_{\alg}}$ which is the torsion free part of the Mordell-Weil group of E/K. According to the BSD conjecture, the quantities $r_{\alg}$ and $r_{\an}:=\min\{k, L^{(k)}_{E/K}(1)\neq 0\}$ should be equal. What I would like to know is whether the set of sub Z-modules (taken in the increasing order of rank) of $Z^{r_{\alg}}$ can be viewed as

a Galois covering of Z, and equivalently if the set $\{L_{E/K}^{(k)}, L_{E/K}^{(k)}(1)=0\}$ (taken in the increasing order of derivation order) can be viewed as a Galois covering of $L_{E/K}$. If so, are these two Galois coverings isomorphic with Galois group $\operatorname{Gal}(K/Q)$? Of course, the objects considered in the present question are to be defined as sets endowed with a coherent topology to be viewed as genuine topological spaces. Perhaps the Zariski topology would do the job considering $\operatorname{spec} Z$ instead of Z, and the set of local factors of $L_{E/K}$ (i.e those that appear in the Euler product thereof) instead of $L_{E/K}$ itself. The key idea is to somehow identify: the group $\Aut_{B}(X)$ of automorphisms of the covering X of the base B preserving B (where B stands for the topological space corresponding to $L_{E/K}$ and X to the $r_{\an}$ topological spaces corresponding to $L_{E/K}, L'_{E/K},...,L^{(r_{\an}-1)}$ in this order) with $\Aut(L_{E/K})$ which, as showed in the link above, is isomorphic to $\operatorname{Gal}(K/Q)$, the group $\Aut_{B'}(Y)$ of automorphisms of the covering Y of the base B' preserving B' (where B' stands for the topological space corresponding to Z and Y to the $r_{\alg}$ topological spaces corresponding to $Z, Z^2,...,Z^{r_{\alg}}$ in this order) with the automorphism group of the isogeny class of E/K which, as showed in the link above, is isomorphic to $\operatorname{Gal}(K/Q)$." If some people here ever vote to close, please give a good reason to do so. Thanks in advance. Edit May 13th 2016: following http://www.math.wisc.edu/~ellenber/MCAV.pdf, it seems that the automorphism group of a $\mathbb{Q}$-curve is actually isomorphic to $\operatorname{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$. I find that rather interesting since I've been suspecting for long that if one calls 'L-function' any element of the set M generated by the Selberg class and automorphic L-functions closed under both the classical product and the Rankin-Selberg convolution, then the set of automorphisms thereof as the group of bijections from M to itself preserving this double structure should be isomorphic to the absolute Galois group of the rational. Still, I never managed to prove this. Can anyone please help me try to clear this out? Edit September 25th 2022: in Grothendieck's conception of Galois theory, the absolute Galois group of a number field is the automorphism group of a fiber functor, which may help reconcile the two points of view (automorphism group of the $\mathbb{Q}$-curve and of the L-function).

Who is attributed with the conjecture that every multiply-perfect number greater than 1 is even?

I know that Descartes is considered to be the first to ask whether or not odd perfect numbers exist (n such that $\sigma(n)=2n$, where $\sigma(n)$ is the sum of divisors of n), and he also discovered several multiply-perfect numbers (n such that $\sigma(n)=kn$ for some integer $k\geq 2$). No odd multiply-perfect numbers greater than one are yet known, and I've heard it called a conjecture that they don't exist several times, but I haven't found an attribution to anyone in particular. Is there an agreed upon origin for the conjecture? The context of my question (please, feel free to skip this): I'm looking for someone to attribute in a paper I'm writing that makes a refinement of this form of conjecture for a generalization of the multiply-perfect numbers. Specifically, let $$\dfrac{\sigma(n)}n=\dfrac{k}m$$ where $\gcd(k,m)=1$ and m is a practical number i.e. $m=1$, or $p_i^{a_i+1}\leq 1+\sigma(p_1^{a_1}p_2^{a_2}...p_i^{a_i})$ for every $i\in[1,\omega(m)]$, where $p_1^{a_1}p_2^{a_2}...p_{\omega(m)}^{a_{\omega(m)}}$ is the canonical prime factorization of m. I call these pad (practical abundancy denominator) numbers, and conjecture that every such number is practical (i.e. a practical number). $\dfrac{\sigma(n)}n$ is called the abundancy of n. It is easy to see that every even perfect number is practical, and every practical number greater than 1 is trivially even, so the conjecture that every perfect number is practical is equivalent to the conjecture that they're all even. From this perspective it's natural to ask whether every multiply-perfect number is practical. I've tested essentially every known multiply-perfect number using the factorizations from Achim Flammenkamp's database and all of them so far are practical, so already this seems like a promising lead. Clearly the multiply-perfect numbers are the special case of the displayed equation where $m=1$, which is trivially practical, so every multiply-perfect number is a pad number. For an idea of their relative size, there are 6484 pad numbers less than 10^6, all of them practical, compared with only 10 multiply-perfect numbers in the same range. An additional fact that makes this conjecture seem quite intuitive is that all small multiples of a practical number are also practical. Specifically, if a is practical and $b\leq \sigma(a)+1$ then ab is practical. Since, k/m is just the abundancy of n in lowest terms, there exists some positive integer r such that $n/m=\sigma(n)/k=r$. When $r=n$, the multiply perfect numbers, we have no idea why every term would be practical, and yet this is the special case I've tested the furthest, and no counterexamples have yet been found. On the other hand, if $r\leq 1+\sigma(m)$ then n is obviously practical. While in retrospective it seems rather intuitive to me, this was a purely numerical observation. Please let me know if you have ideas about this problem, since I believe it has the potential to remain open for a long time, but someone to attribute is what I'm asking for, since right now I feel I have very few people to attribute in my paper. This is for my first paper, which I think I will try to have published in Experimental Mathematics, since computational experiments were the method by which I reached this generalization. If you have strong opinions about other papers or people who should be attributed then please mention them at least in the comments. I'm not looking to downplay anyone's contributions, and I realize the importance of showing how your work ties in with that of others. Edit: Note that the same conjecture appears to hold with $\sigma(m)$ replaced by $\sigma^*(m)=\prod_{i=1}^{\omega(m)}(p_i^{a_i}+1)$, the sum of the unitary divisors of n, which might be simpler to work with.

Floors of rationals to powers: Infinite number of primes?

Let $r=a/b$ be a rational number in lowest terms, larger than 1, and not an integer (so $b > 1$). Q. Does the sequence $$ \lfloor r \rfloor, \lfloor r^2 \rfloor, \lfloor r^3 \rfloor, \ldots, \lfloor r^n \rfloor, \ldots$$ always contain an infinite number of primes? For example, for $r=13/4$, $$(r,r^2,r^3,r^4,r^5, \ldots) = (3.25, 10.56, 34.33, 111.57, 362.59, \ldots)$$ and so the floors are $$(3, 10, 34, 111, 362, \ldots)$$ The next prime after 3 occurs at $$\lfloor r^{34} \rfloor = 2535328703512709 71$$ and I only find four primes up to $\lfloor r^{1000} \rfloor$.

Distribution of the sum of the m smallest values in a sample of size n

Let $\mathbf X = [X_1, X_2, \ldots, X_n]^\mbox{T}$ be a vector random variable drawn from a known distribution with CDF $F(x)$. The CDF for the minimum value in $\mathbf X$ is clearly $P[\min_{i=1\ldots n} X_i \leq x]$ $=$ $1 - \prod_{i=1\ldots n} P[X_i>x]$ $=$ $1 - (1 - F(x))^n$. The expected value for the minimum value in $\mathbf X$ is therefore $\int_0^\infty 1 - (1 - (1 - F(x))^n)dx$. I am interested in the sum of the m smallest values (i.e., order statistics) in $\mathbf X$. It seems like the expected value for the sum should look something like $\sum_{i=0}^{m-1} \int_0^\infty 1 - (1 - (1 - F(x))^{n-i})dx$, however, my intuition tells me that that conflicts with the independence of the events. I therefore have two questions: What is the expected value of the sum of the m smallest values in $\mathbf X$? What is the PDF and/or CDF of the sum? An answer to #2 alone would be sufficient.

An open problem in convex geometry

Is it possible to find four norms $\| \cdot\|_k$ $(1 \leq k \leq 4)$ on the plane such that a three-dimensional normed space containing four subspaces isometric to these normed planes does not exist? An equivalent statement: Is it possible to find four 0-symmetric convex bodies in the plane such that a three-dimensional 0-symmetric convex body containing four central sections linearly equivalent to these four bodies does not exist? This seems to be an old problem, but I'm not sure of its origin. The earliest reference I've found is Rolewicz, S., Plane sections of centrally symmetric convex bodies. Israel J. Math. 4 1966 135-138. Does anyone know the status of this problem? Some earlier references? Just for completeness, let me add that Bessaga proved (C. Bessaga,A note on universal Banach spaces of a finite dimension, Bull. Acad. Polon. Sci.6 (1958), 97-101.) that Given $n > 2$, it is possible to find $N = N(n)$ norms $\| \cdot\|_k$ $(1 \leq k \leq N)$ on the plane such that an n-dimensional normed space containing N subspaces isometric to these normed planes does not exist. Rolewicz mentions that it is not clear whether we can take $N(n) = n+1$. Added on 08/01/2014. Trying to guess what possible four normed planes cannot be linearly and isometrically embedded in any one three-dimensional normed space: Does there exist a three-dimensional centrally symmetric convex body that contains four central sections that are linearly equivalent to a circle, a square, a regular hexagon, and a regular octagon?

Point singularity of a Riemannian manifold with bounded curvature

Suppose you have an incomplete Riemannian manifold with bounded sectional curvature such that its completion as a metric space is the manifold plus one additional point. Does the Riemannian manifold structure extend across the point singularity? (Penny Smith and I wrote a paper on this many years ago, but we had to assume that no arbitrarily short closed geodesics existed in a neighborhood of the singularity. I was never able to figure out how to get rid of this assumption and still would like someone better at Riemannian geometry than me to explain how. Or show me a counterexample.) EDIT: For simplicity, assume that the dimension of the manifold is greater than 2 and that in any neighborhood of the singularity, there exists a smaller punctured neighborhood of the singularity that is simply connected. In dimension 2, you have to replace this assumption by an appropriate holonomy condition. EDIT 2: Let's make the assumption above simpler and clearer. Assume dimension greater than 2 and that for any r > 0, there exists 0 < r' < r, such that the punctured geodesic ball B(p,r'){p} is simply connected, where p is the singular point. The precludes the possibility of an orbifold singularity. ADDITIONAL COMMENT: My approach to this was to construct a differentiable family of geodesic rays emanating from the singularity. Once I have this, then it is straightforward using Jacobi fields to show that this family must be naturally isomorphic to the standard unit sphere. Then using what Jost and Karcher call "almost linear coordinates", it is easy to construct a C^1 co-ordinate chart on a neighborhood of the singularity. (Read the paper. Nothing in it is hard.) But I was unable to build this family of geodesics without the "no small geodesic loop" assumption. To me this is an overly strong assumption that is

essentially equivalent to assuming in advance that that differentiable family of geodesics exists. So I find our result to be totally unsatisfying. I don't see why this assumption should be necessary, and I still believe there should be an easy way to show this. Or there should be a counterexample. I have to say, however, that I am pretty sure that I did consult one or two pretty distinguished Riemannian geometers and they were not able to provide any useful insight into this.

An infinite, amenable, finitely presentable group with no non-trivial finite quotients

My question is a simple one: is there a group with the properties in the title? In the absence of the 'finitely presentable' hypothesis, an example is provided by Juschenko--Monod's construction of a finitely generated, infinite, simple, amenable group. On the other hand, all the standard examples that I know of finitely presentable groups without finite quotients seem to be non-amenable. There are a number of participants on MO who have constructed interesting examples of amenable groups. My guess is that the answer to this question is unknown, but if so I'd also be interested in informed conjectures. Is it at all probable that such a group doesn't exist?

Conjectures in classical harmonic function theory

Because I'm doing research in the area of harmonic function theory I would like to know are there any conjectures in the theory of harmonic functions in $\mathbb{R}^{n}$ still open. I know that there are many conjectures related to manifolds, but I don't want them. I want conjectures that are just related to harmonic functions on open sets in $\mathbb{R}^{n}$. Are there some really famous ones and long open?

Convergence in L^2 of iterated expectations

Take a probability space $(\Omega,\mathcal{F},\mathbf{P})$ and random variable $X \in L^2(\Omega,\mathcal{F},\mathbf{P})$. Define the iterated expectations of X as follows: $X_0 = X$, and, inductively, $X_k = \mathbf{E}[X_{k-1} \, | \, \mathcal{G}_k]$, where $\mathcal{G}_k \subseteq \mathcal{F}$ is some σ-algebra. Assume that all the $\mathcal{G}_k$ come from some finite set of distinct σ-algebras. In words, we are repeatedly taking conditional expectations with respect to various information. Can we conclude that the sequence (X_k) converges to some limit in L^2? The paper [1] says the question seems to be open (as of its publication) and reviews some of the literature, going back to Rota's Alternierende Verfahren. (The contribution of the paper is to show that if we drop the restriction of finitely many distinct σ-algebras, the statement is not true.) Has there been any progress since? [1] M. Akcoglu and J. King. An example of pointwise non-convergence of iterated conditional expectation operators. Israel J. Math. 94 (1996). This paper was pointed out to me by Anthony Quas at a related question -- When do iterated conditional expectations converge?

Ramanujan's problem 754 still open?

In addition to the MO question The Ramanujan Problems. , I would like to ask the following. Problem 754 from the list of the Ramanujan's problems (http://www.imsc.res.in/~rao/ramanujan/collectedpapers/question/q754.htm) asks to show that $$e^xx^{-x}\pi^{-1/2}\Gamma(1+x)=(8x^3+4x^2+x+E)^{1/6},$$ where E lies between $\frac{1}{100}$ and $\frac{1}{30}$ for all positive values of x. According to http://citeseerx.ist.psu.edu/viewdoc/summary?doi=10.1.1.39.9228 (The Problems Submitted by Ramanujan to the Journal of the Indian Mathematical Society, by Bruce C. Berndt, Youn--seo Choi and Soon-Yi Kang) this problem was still open in 1997. What is the status of this problem at present?

An integral related to the Euler gamma function

The question is from the paper http://arxiv.org/abs/1312.7115 (A curious formula related to the Euler Gamma function, by Bakir Farhi): is it possible to express the integral $$\eta=2\int\limits_0^1 \ln{(\Gamma(x))}\cdot \sin{(2\pi x)}\,dx= 0.7687478924\ldots$$ in terms of the known mathematical constants as $\pi,\,e,\,\gamma,\;\ln{\pi},\, \ln{2},\,\Gamma{(1/4)}\ldots$? It is shown in the paper that $$\frac{\ln{1}}{1}-\frac{\ln{3}}{3}+\frac{\ln{5}}{5}-\ldots=\pi\ln{(\Gamma{(1/4)})}-\frac{\pi^2}{4}\eta-\frac{\pi}{2}\ln{\pi}-\frac{\pi}{4}\ln{2}.$$ So the question actually asks whether one can give a closed-form expression for the series in the l.h.s. in terms of the known mathematical constants.

Objections to and arguments for the simplicity of all Riemann zeros

It seems to be that the simplicity of all the zeros is quite widely accepted as a working hypotheses, and it is known that a positive proportion are as such. Titchmarsh explains in the last chapter on RH that the weak Mertens hypothesis, $M(x)=O(x^{1/2})$, implies that all zeros are simple. Though I think this is conjectured to be false by many authors. Is there a weaker bound whose optimality is known to imply that not all zeros are simple? Given the classical estimate $N(\sigma, T)=O(T^{4\sigma(1-\sigma)+\epsilon})$ combined with the fact that the number of solutions to $\zeta(s)=z$ in any rectangle of height T contained in $1/2\leq \sigma\leq 1$ is proportional to T, for any $z\neq 0$, simplicity of the zeros suggests that the derivative must vanish vastly more frequently in each such rectangle else one could presumably tie the number of such solutions to the number of zeros up to height T, for all sufficiently small $|z|$, by Rouche's theorem. One might therefore conjecture that $ \inf|\rho_{\zeta}-\rho_{\zeta'}|=0$ (is this known perhaps?). An old theorem of MacDonald (Whittaker and Watson, p131) says that the number of zeros of an analytic function on the interior of a simple closed curve on which the modulus of f is constant exceeds that of it's derivative by one. It can also be seen that the derivative necessarily vanishes on the largest such curve by the open and inverse mapping theorems. In the case of $\zeta(s)$ I'd expect that the largest of such curves around each zero would become small for large T, so I wonder if something in this direction is known? Anyway, as Titchmarsh points out, Ω-theorems for $M(x)$ seem to be more difficult to obtain than those for the prime counting functions and, since a significant distinction between the problems is that of the order of the zeros, I would like to enquire specifically about anything that is known in either direction, on any other hypotheses.

Determine or estimate the number of maximal triangle-free graphs on n vertices

Among the collections of the open problems of Paul Erdős on the website of Professor Fan Chung, there is one called "number of triangle-free graphs". http://www.math.ucsd.edu/~erdosproblems/erdos/newproblems/NumberOfTriangleFreeGraphs.html Open Problem: Determine or estimate the number of maximal triangle-free graphs on n vertices. Is any one working on this problem? Any known related results? Now I am considering about using a "connection game" method to solve this problem: Given a set of n players, each one chooses to connect to other nodes, if any two neighbors of it connect a new edge(which means there would form a triangle), it has to choose delete either edges with those two neighbors. Then the question is how many different topology connections does it have? Any comments on this method?

Which region in the plane with a given area has the most domino tilings?

I just finished teaching a class in combinatorics in which I included a fairly easy upper bound on the number of domino tilings of a region in the plane as a function of its area. So this led to this question, which I suspect is an open problem: Does a $2n \times 2n$ square have the most domino tilings among all regions with area $4n^2$? I aired this question in a mailing list, which is one reason that I think that it's an open problem. The discussion there did lead to a great answer from Rick Kenyon, who says that using his methods, the conjecture is asymptotically true for dilated rectilinear regions. (In other words, if you take any fixed polyomino and dilate it by a sufficiently large factor, then it will have fewer tilings than a square with the same area or very slightly less area.) Still, I just came up with the question in my class, so I don't really know if it's open or previously stated. (This is my excuse for posting it MO.) I Googled some, without success. It is also easy to pose generalizations: (1) The inequality might also hold for regions that map to the plane with multiple sheets (immersions) or branch points, at least when such regions are topological disks and the branch points are at vertices of the tiling by unit squares. (Kenyon's methods might also apply to these cases.) (2) Does the d-dimensional cube $[0,2n]^d$ have the most tilings by domino bricks, among all regions in $\mathbb{R}^d$ with volume $(2n)^d$? (3) Given an integer $k > 2$, does a $kn \times kn$ square have the most tilings by $k \times 1$ rectangles, among regions with area k^2n^2? (4) Mutual generalizations of (1)-(3), and tilings by a rectangular brick with some other shape. Kenyon's work is a (deep) extension of the permanent-determinant method of Kasteleyn and Percus to count matchings of a planar graph, so it would not apply to cases (2) and (3).

Is there an associative metric on the non-negative reals?

Recall that a function $f\colon X\times X \to \mathbb{R}_{\ge 0}$ is a metric if it satisfies: definiteness: $f(x,y) = 0$ iff $x=y$, symmetry: $f(x,y)=f(y,x)$, and the triangle inequality: $f(x,y) \le f(x,z) + f(z,y)$. A function $f\colon X\times X \to X$ is associative if it satisfies: associativity: $f(x,f(y,z)) = f(f(x,y),z)$. If $X=\mathbb{R}_{\ge 0}$, then it might be possible for the same function to be a metric and associative. Is there an associative metric on the

non-negative reals? Note that these demands actually make X into a group. The element 0 is the identity because $f(f(0,x),x) = f(0,f(x,x)) = f(0,0) = 0$ by associativity and definiteness, so again by definiteness $f(0,x) = x$. Every element is its own inverse because $f(x,x)=0$. In fact, the following question is equivalent. Is there an abelian group on the non-negative reals such that the group operation satisfies the triangle inequality? Note also that the answer is yes if $X=\mathbb{N}$, the non-negative numbers! Click here for a spoiler. "Also known as nim-sum." The question is originally due to John H. Conway. To my knowledge, the question is unsolved even for $X = \mathbb{Q}_{\ge 0}$, but he does not seem to care about that case. The spoiler above does extend to the non-negative dyadic rationals $\mathbb{N}[\frac 12]$, but apparently not to $\mathbb{N}[\frac 13]$.

Conjecture of a subset of Wang tile which might be decidable

From the two papers proving the undecidability of Wang tile in 1966 by Berger and in 1971 by RM Robinson, the tiles used in proving undecidability has a general common feature: The left color and right color do not uniquely determine the top color and bottom color. The tiles involved in practice in material science and physics for one big problem is actually more restricted and the tiling problem might actually turn out to be decidable. So the subset of Wang Tile is lattice tiles, shown in my previous post: Reference for Wang Tile The general feature of the tile is that the pair (left color, right color) uniquely determine the pair (top color, bottom color). I conjecture that a subset of Wang tiles which satisfies the restriction above might turn out to be decidable... Any thought on this problem? Thank you.

What is Chern-Simons theory expected to assign to a point?

Let G be a compact, connected, (simply connected?) Lie group and let $k \in H^4(BG, \mathbb{Z})$ be a cohomology class. Witten showed, at a physical level of rigor, that this data determines a 3-dimensional topological quantum field theory (going down to surfaces), Chern-Simons theory. Later other authors (Reshetikhin-Turaev, ???) described how to extend this theory down to 1-manifolds. It's known that such a theory is determined by what it assigns to a circle S^1, which must be a modular tensor category; this category can be described either as a certain category of representations of the loop group LG at level k or as a certain category of representations of the quantum group $U_q(\mathfrak{g})$, where q is a suitable function of k. The relationship between these two descriptions is unclear to me. My impression is that it's expected that Chern-Simons theory extends all the way down to 0-manifolds; that is, that it is a fully extended TQFT. By Lurie's classification, such a theory is completely determined by what it assigns to a point, which is a fully dualizable object in a suitable 3-category. What are some conjectural descriptions of this object? The nLab is somewhat vague on this subject. Here's what I know: The corresponding object for 3-dimensional Dijkgraaf-Witten theory is known, although I'm not sure exactly who this is due to. Here G is replaced by a finite group and k is thought of as a class in $H^3(BG, \text{U}(1))$. k is used to twist the associator on the monoidal category of G-graded vector spaces, giving a monoidal category (in fact a fusion category) of "twisted G-graded vector spaces," to be thought of as a fully dualizable object in the 3-category of monoidal categories and bimodule bicategories over these (Douglas-Schommer-Pries-Snyder?), and I think this is what fully extended 3-dimensional Dijkgraaf-Witten assigns to a point. Freed-Hopkins-Lurie-Teleman generalized this construction to the case that G is a torus; here G-graded vector spaces are replaced by skyscraper sheaves on G. I don't know if this is expected to generalize.

A generalization of Cauchy's mean value theorem.

The following simple theorem is known as Cauchy's mean value theorem. Let γ be an immersion of the segment $[0,1]$ into the plane such that $\gamma(0) \ne \gamma(1)$. Then there exists a point such that the tangent line at that point is parallel to the line passing through $\gamma(0)$ and $\gamma(1)$. So the boundary values of an immersion determine a direction such that for any immersion of a segment with given boundary values there exists a tangent line parallel to the direction. I would like to propose the following conjecture, generalizing this statement. Instead of immersions of a segment we consider immersions of a compact manifold M^n with non-empty boundary ∂M into ${\mathbf R}^{n+1}$. For a map $f\colon \partial M \to {\mathbf R}^{n+1}$ we consider the space $L(f)$ of all immersions $g\colon M \to {\mathbf R}^{n+1}$ such that $g|_{\partial M}=f$. The conjectural claim is the following: If f is sufficiently generic, then for every connected component L_0 of the space $L(f)$ there exists a hyperplane direction l such that for any immersion g from L_0 l is parallel to the tangent plane to $g(M)$ at some point. If the conjecture is true then it is very interesting how l depends on g.

On Polynomials dividing Exponentials

EDIT, May 2015: in the second edition of the relevant book, the question was corrected, a single number had been mis-typed. The corrected question (thanks to Max) is to find all positive integer pairs such that $$ m^2 - 1 \; | \; 3^m + \left(n! - 2 \right)^m. $$ $$ $$ The version that caused me all that misery was $ m^2 - 1 \; | \; 3^m + \left(n! - 1 \right)^m. $ EDIT, 2010: it turns out that no answer to this is known, as the authors of the book it is in have now confirmed they do not know how to do it. Will Jagy. ORIGINAL: I have been wondering if there exist some general techniques to attack problems in which a polynomial divides and exponential equation. The motivation of this question came when trying to solve the following problem: Find all positive integers "m such that m^2-1 divides 3^m+5^m I haven't been able to come with a proof, and I am really considering the possibility that it cannot be solved using "elementary" methods. I would really apprecciate

some references (if there are any) to the general question as well as the solution to this very particular case.

Integral straight-line embeddings of planar graphs

Wikipedia says (in the article on Fáry's theorem), "Heiko Harborth raised the question of whether every planar graph has a straight line representation in which all edge lengths are integers. The answer remains unknown as of 2009." The reference is this: Kemnitz, Arnfried, and Heiko Harborth. "Plane integral drawings of planar graphs." Discrete Mathematics 236.1 (2001): 191-195. (Elsevier link) It is known that every n-vertex planar graph has a planar straight-line grid drawing on an $O(n) \times O(n)$ grid. But of course integer vertex coordinates do not imply integer edge lengths! The Kemnitz-Harborth article concludes with this sentence: "It seems to be a very hard problem to prove that every pentagon with sides of integral length contains an inner point with rational distances to its vertices." Here are my questions: Q. Have there been advances on this problem in the last five years? Perhaps for special cases beyond cubic graphs? Any progress on the specific pentagon problem identified above? Addendum. User fidbc cited two recent papers exhibiting progress: Biedl, Therese C. "Drawing some planar graphs with integer edge-lengths." CCCG. 2011. She shows that planar bipartite, series-parallel graphs, graphs with aboricity 2, outerplanar graphs, and-most interestingly-that every planar graph of degree at most four, but which is not 4-regular, has an integral embedding. Sun, Timothy. "Drawing some 4-regular planar graphs with integer edge lengths." CCCG. 2013. Timothy extends Therese's work and captures various families of (but not all) 4-regular planar graphs. Finally, TMA's mentions the four-square-corners problem, which is described in this MathWorld article, which says, "J.H. Conway and R. Guy found an infinite numbers of solutions to the problem of three such distances being integers."

$\operatorname{SL}_2(\mathbb R)$ Casson invariant?

$\DeclareMathOperator\SL{SL}$Casson's invariant is an invariant of a homology 3-sphere, obtained by “counting” representations of the fundamental group into $\operatorname{SU}(2)$. I was wondering if there is an analogous invariant counting representations into $\SL(2,\mathbb R)$? Curtis has an invariant counting representations into $\SL(2,\mathbb C)$. These invariants are obtained by taking a Heegaard splitting of the manifold, and considering the intersection of the representation varieties of the two handlebodies in the representation variety of the Heegaard surface. Casson has to perturb the resulting varieties to make them transverse, then counts the intersections. Curtis counts only the finite points of intersection using algebraic geometry to resolve any singularities, and ignoring any higher dimensional components of the intersection. Then they both have to show that this count is invariant under stabilization of Heegaard splittings, and therefore an invariant of the manifold. I was wondering whether one could combine the two approaches to get an analogous invariant in the case of $\SL(2,\mathbb R)$ representations? One would throw away higher dimensional components of intersection of the $\SL(2,\mathbb R)$ varieties of the two handlebodies, and perturb near the isolated intersections to get a count of intersection points. If this works, what about making an analogous Floer theory, by counting holomorphic disks between finite intersection points? I have't done a literature search, but I suspect this is an open question.

Generating random finite groups

I would like a method to efficiently generate a random finite group of a given order n. If there are $g(n)$ non-isomorphic groups of order n, ideally each group would occur with probability $1/g(n)$. So if $n=64$, each of the 267 groups would be generated with equal probability. ($g(n)$ is A000001 in OEIS.) Groups of order $n=2^k$ would be of special interest. This is far from my expertise, and my searches must be using the wrong terminology, because I have not found such methods. I'd appreciate pointers-Thanks! Addendum. The comments indicate that this appears to be an open problem, with little chance of resolution in the near future. Now so tagged.

Rost Correspondence and minimal Pfister-Neighbors

In http://www.math.uiuc.edu/K-theory/0357/ Karpenko utters the following: Conjecture 1.6. If an anisotropic quadric $X = Q$ possesses a Rost correspondence, then the quadratic form (defining X) is a minimal Pfister neighbor. Since the Paper has been released 15 years ago, I wonder if there has been made any progress on the conjecture. Everything regarding Rost-Projectors is defined within the paper. I am quite new to the subject and I am "working" myself through most of the papers in order of their release, so it might be that my question is obsolete today. On the other hand, there is also a remark in "Rost Projectors and Steenrod Operations" by Karpenko and Merkurjev from 2002 that the problem is still not solved, except for the cases of $dim(X) = 3,7$.

Are there Ricci-flat riemannian manifolds with generic holonomy?

This may well be an open problem, I'm not sure. In Berger's classification (refined by Simons, Alekseevsky, Bryant,...) of the holonomy representations of irreducible non-symmetric complete simply-connected riemannian manifolds, there are some cases which imply Ricci-flatness: namely, $\mathrm{SU}(n)$ (Calabi-Yau) in dimension $2n$, $\mathrm{Sp}(n)$ (hyperkähler) in dimension $4n$, G_2 in dimension 7 and $\mathrm{Spin}(7)$ in dimension 8. A natural question is the converse: whether Ricci-flatness implies a reduction of the holonomy. The other holonomy representations are known not to be Ricci-flat: $\mathrm{Sp}(n)\cdot \mathrm{Sp}(1)$ (quaternionic kähler) is known to be Einstein with nonzero scalar curvature, and in the case of $\mathrm{U}(n)$ in dimension $2n$ (Kähler) it is known that if a Kähler manifold is Ricci-flat then the holonomy is contained in $\mathrm{SU}(n)$, so that it is Calabi-Yau. So the remaining question is whether there exists any Ricci-flat riemannian manifolds with generic holonomy $\mathrm{SO}(n)$ in dimension n. I would like to know the present status of this question and if it's still open what the experts think: do people expect examples of Ricci-flat riemannian manifolds with generic holonomy? Bonus question: How about if the manifold is pseudoriemannian? Added Thanks to Igor's answer below, here are some further remarks. The question needs to be refined. The riemannian analogue of the Schwarzschild metric on $\mathbb{R}^2 \times S^2$ is an example of a complete, simply-connected noncompact Ricci-flat metric with generic holonomy. So the question is about compact examples. In fact, in Berger's 2003 book A panoramic view of Riemannian geometry (page 645) one reads at the bottom of the page: It remains a great mystery that no Ricci flat compact manifolds are known which do not have one of these special holonomy groups.

Factorials in Pascal's triangle

I asked this question of Keith Conrad, and he suggested that I try posting here. One of my students observed that the only instances of factorials in the interior of Pascal's triangle are $\binom{4}{2}=3!$ and $\binom{10}{3}=\binom{16}{2}=5!$. I checked the first 500 rows, and he's right up to that point. This is a special case of the apparently unsolved problem of finding non-trivial solutions to $n!=a!b!c!\dots$ The special feature here is that I need $(a+b)!=a!b!c!$, and that seems like a special enough case to have been treated by someone. Unfortunately, literature searches have been fruitless, because every paper about Pascal's triangle contains the word "factorial" somewhere. My best idea (which I can't make work) is to show that the powers of 7 in the equation $(a+b)!=a!b!c!$ can't be made to match up unless neither side is a multiple of 7. Then exhaustive searching can show that the above are the only non-trivial solutions. Thanks greatly for any ideas that anyone might have.

Packing space by cones: Translates best?

Let C be a right circular cone, the convex hull of a unit-radius disk and a point directly above the disk center at height h. Is the most dense packing of $\mathbb{R}^3$ achieved by translates of C and its negative,* $-C$, i.e., upside-down C? Or is it known that rotations of the cones permit achieving a denser packing? * Barany, Imre, and Jiri Matousek. "Packing cones and their negatives in space." Discrete & Computational Geometry 38.2 (2007): 177-187. (Springer link) Here is TMA's idea: (27Jun14). Conjecture by Wlodek Kuperberg (see the comments), the expert on the topic: "For a generic cone, the densest packing by translates of the cone and its point-reflection is perhaps the best one." Now marked as an open problem.

Is there a non-zero ghost map between finite suspension spectra?

A morphism $f\colon X\to Y$ of spectra such that for every integer n the induced map $\pi_n(f)\colon\pi_n(X)\to\pi_n(Y)$ on stable homotopy groups is zero is called a ghost map. Not every ghost map f is the zero object of the abelian group $\operatorname{Hom}_{SH}(X,Y)$ (more precisely, its image $\bar f\in \operatorname{Hom}_{SH}(X,Y)$ in the stable homotopy category SH). Suppose $X=\Sigma^\infty A$ and $Y=\Sigma^\infty B$ are the suspension spectra of finite CW-complexes, let $f=\Sigma^\infty f'$ for a map $f'\colon A'\to B'$ and suppose that f is a ghost map. Is f necessarily zero in this case?

Is it possible to dissect a disk into congruent pieces, so that a neighborhood of the origin is contained within a single piece?

Problem: is it possible to dissect the interior of a circle into a finite number of congruent pieces (mirror images are fine) such that some neighbourhood of the origin is contained in just one of the pieces? It may be conceivable that there is some dissection into immeasurable sets that does this. So a possible additional constraint would be that the pieces are connected, or at least the union of connected spaces. A weaker statement, also unresolved : is it possible to dissect a circle into congruent pieces such that a union of some of the pieces is a connected neighbourhood of the origin that contains no points of the boundary of the circle? This is doing the rounds amongst the grads in my department. So far no one has had anything particularly enlightening to say - a proof/counterexample of any of these statements, or any other partial result in the right direction would be much obliged! Edit: Kevin Buzzard points out in the comments that this is listed as an open problem in Croft, Falconer, and Guy's Unsolved Problems in Geometry (see the bottom of page 87).

Does linearization of categories reflect isomorphism?

Given a category C and a commutative ring R, denote by RC the R-linearization: this is the category enriched over R-modules which has the same objects as C, but the morphism module between two objects x and y is the free R-module on $\operatorname{Hom}_C(x,y)$. Thus in RC we allow arbitrary R-linear combinations of morphisms from the original category C. Question: if two objects in x, $y \in C$ are isomorphic in RC, are they already isomorphic in C? I do not know the answer to this question for any nontrivial ring R, but I'm particularly interested in $R=\mathbb{Z}$ and $R=\mathbb{Z}/2\mathbb{Z}$. What's obviously not true is that every isomorphism in RC comes from an isomorphism in C (take $-id_x$). (Thus the word "isomorphism" in the title refers to a relation on objects rather than to a property of morphisms.) Of course, it is enough to consider categories C with two objects x, y, but we cannot assume that C is finite. It's fairly elementary to see that if x and y are isomorphic in RC then in C, x is a retract of y and vice versa, but the latter does in general not imply that $x \cong y$. A more catchy way of phrasing this problem is: can we always classify objects in a category up to isomorphism by means of functors taking values in R-linear categories? (The inclusion $C \to RC$ is the universal such functor.) Edit: A lot of people have posted an "answer" that wasn't, and deleted it, so here's something that will not work, to save others going down the same road. I said that we cannot assume that the category is finite; in fact, it must be infinite. Here is an elementary argument: Since x and y are mutual retracts, there are maps $f,\;f'\colon x \to y$ and $g,\;g'\colon y \to x$ with $fg=\operatorname{id}$ and $g'f'=id$. Consider the powers of $fg' \in \operatorname{End}(y)$. If $\operatorname{End}(y)$ is finite then $(fg')^n = (fg')^m$ for some $m \neq n$; since fg' has a right inverse (viz, $f'g$), we must have that $(fg')^n=\operatorname{id}$ for some $n>0$. So we see that g' has not only a right inverse (f') but also a left inverse: $(fg')^{n-1}f$. So they are the same and g' is already an isomorphism.

If $2^x $and 3^x are integers, must x be as well?

I'm fascinated by this open problem (if it is indeed still that) and every few years I try to check up on its status. Some background: Let x be a positive real number. If n^x is an integer for every $n \in \mathbb{N}$ then x must be an integer. This is a fun little puzzle. If 2^x, 3^x and 5^x are integers then x must be an integer. This requires fairly sophisticated tools, and can be derived from the results in e.g. Lang, Algebraic values of meromorphic functions. II., Topology 5, 1966. Finally, if all you know is that 2^x and 3^x are integers, then as far as I know it is not known if x is forced to be an integer (unbelievable, isn't it?). Although of course one can never be certain, I am quite sure this was still the case as recently as 2003. So the question is, is that still an open problem, and is there any sort of relevant progress that may provide some hope?

A possible minimal aperiodic set of corner Wang Tile

From one of my previous question Aperiodic set of corner Wang Tile (although it is put on hold), I realize there is a systematic way to construct aperiodic corner type of Wang tile from edge type aperiodic Wang Tiles. But what I am more interested in is this: For edge type of Wang tile, there is common knowledge of a very small set of Wang tile with 13 elements: http://www.sciencedirect.com/science/article/pii/S0012365X96001185 (doi: 10.1016/S0012-365X(96)00118-5 or with 14 elements: http://www.sciencedirect.com/science/article/pii/0012365X9500120L (doi: 10.1016/0012-365X(95)00120-L It seems there is a competition on this arena of achieving smaller set of aperiodic edge type of Wang tiles. On the other hand, I interested on a documented small set of corner Wang tiles. Do someone know some reference on this? Thank you:)

reduction to np hard ordering problem

I am trying to show a reduction from a problem of ordering problem to an np-hard problem that has approximation poly-time algorithm. My problem is: I have M auctions and in each auction I have N bidders. A bidder can bid in all the auctions until he wins one, but if he won one of the auctions he can't win other items. assuming that the auctioneer that plans the auctions has information about all the values that the bidders are willing to bid on all the items before the auctions, he needs to find an ordering that maximizes his profit - meaning the sum he get from all the auctions. I tried finding an NP-hard problem that I can reduct this problem to, but with no succes. I thought about max-weighted-IS problem by setting the vertices as : Xij - the value that bidder i is willing to bid on item j, and then add edges between all the vertices that have the same j-th value and between all the vertices that have the same i-th value, thus promising that the vertices in the independent set will have preserve the constraing of the auctio, but the problem in this reduction is that given an max weighted indepndent set the max ordering is not neccesserily optimal. Any help would be appriciated. Thanks

Is the fixed point property for posets preserved by products?

Recall that a partially ordered set (poset) P has the fixed point property (FPP) if any order preserving function $f:P\longrightarrow P$ has a fixed point. Theorem. Suppose P and Q are posets with the FPP and at least one of them is finite. Then $(P\times Q)$ has FPP. Note: $(a,b)\le(c,d)$ if and only if $a\le c$ and $b\le d$. Question. Suppose P and Q are two infinite posets with the FPP. Does $(P\times Q)$ have the FPP ?

Does S^4 have a "symplecto-homeomorphic" structure?

The 4-sphere cannot be a symplectic manifold. In particular, it does not admit an atlas whose transition maps are symplectomorphisms $(\mathbb{R}^4,\omega_\text{std})\to(\mathbb{R}^4,\omega_\text{std})$. Eliashberg-Gromov proved that if the C^0-limit of symplectomorphisms is a diffeomorphism, then it is a symplectomorphism. We can now ask about the next best thing: Does S^4 have a symplectohomeomorphic structure, i.e. are there charts (equipped with the standard symplectic form on $\mathbb{R}^4$) whose transition maps are homeomorphisms that are C^0-limits of symplectomorphisms? (This question may have originated from Alan Weinstein, who told me it after conversations concerning symplectic rigidity.)

Non-negative, monotone polynomial sequences without combinatorial interpretation

I am wondering what sequences of integers there are, that are known to grow polynomially, are non-negative, monotone but lacks a combinatorial interpretation. By combinatorial interpretation, they are given by counting some discrete class of objects, (say lattice points in a polytope, Young tableaux, lattice paths, etc). For example, the function $k \mapsto c^{k\lambda}_{k\mu,k\nu}$ where c is the Littlewood-Richardson coefficient, λ,μ,ν are partitions, and $k\geq0$ is an integer, is a sequence that satisfies all above properties, but it has a combinatorial description. Replace c with the more general Kronecker coefficients, and we obtain a sequence of integers that satisfy all listed properties, and it is one of the big unsolved problems in combinatorial representation theory to give a combinatorial description of the Kronecker coefficients. Another non-example is the super-Catalan numbers, $$C(m,n) = \frac{(2m)!(2n)!}{(m+n)!m!n!}$$ which lacks a combinatorial description in general, and is non-negative, integer and monotone for each fixed m. However, the growth is not polynomial (the case $m=1$ corresponds to 2 times the usual Catalan numbers). Of course, there are many sequences of numbers above, so to clarify, I mean sequences that belong to some natural family, parametrized by some auxiliary parameter(s), for example partitions, as above.

Is there a finite-index finite-depth II$_1$ subfactor which is more than 7-super-transitive?

Background: See Noah and Emily's posts on subfactors and planar algebras on the Secret Blogging Seminar. There are plenty of examples of 3-super-transitive (3-ST) subfactors; Haagerup, $S_4 < S_5$, and others. There's exactly one known example of a 5-ST subfactor, the Haagerup-Asaeda subfactor, and one 7-ST subfactor, the extended Haagerup subfactor. Below index 4 there are the A_n and D_n families, which are arbitrarily super-transitive. Ignore those; I'm just interested above index 4. Is there anything that's even more super-transitive?

Gauss Codes that produce classical knots as opposed to virtual knots

I have been doing some research in Gauss codes and have been reading Kauffman's paper Virtual Knot Theory. In section 3.3, Theorem 2, he states that If K is a virtual knot whose underlying Gauss code is planar and whose sign sequence is standard, then K is equivalent to a classical knot. He then goes on to say that "The fundamental problem in Gauss codes is to give an algorithm for determining whether a given code can be realized by a planar shadow." One problem I have is that I can't figure out what exactly the word standard means in the theorem - he says he will define it later and never does. And does he actually solve this "fundamental problem" in the rest of the section 3.3. If anyone knows a technical definition of standard, I would be very appreciative. The point is to figure out if the the follow question is open: Given a Gauss Code, is there an (explicit) algorithm for detecting if it can be realized as a classical knot? So if you know that it is or is not open, I would love to know too. In the case that it is known, a reference would be wonderful too. Thanks.

Randomly placing nonoverlapping unit cuboids

Suppose one places unit cuboids of dimension d with min-corners uniformly distributed to lie in $[0,n]^d$, but with cuboid (strict) overlap forbidden. At some point, the region is "saturated," without room for more cuboids to fit. For example, for $d=2$ squares in $[0,10]^2$, it appears that about 63 squares on average will fit (whereas $n^d=100$ could fit): So here the packing density is about 63%. Q. Is the expected number of cuboids known, as a function of n and of d? Is the growth rate in n known for fixed d? Update. Benjamin Dickman identified the $d=1$ version as the Rényi parking problem, where it is known that, for large n, the packing density approaches $m \approx 0.7476$, i.e., the expected number of cars(intervals) is $m n$. It is conjectured that in $d=2$, the expected packing density approaches $m^2 \approx 0.559$. Yoav Kallus points to a related paper that uses the apt phrase sequential random packing for the process.

Inverted pair of complex analytic families

I read the following "problem" in an old set of notes of Morrow and Kodaira which focused on deformations of complex manifolds: Find a pair of complex analytic families $\lbrace M_t\rbrace$ and $\lbrace N_t\rbrace$ with $|t|<1$ such that $M_t=N_0$ for $t\ne 0$ and $N_t=M_0$ for $t\ne0$, with $M_0\ne N_0$. (Every manifold assumed compact.) As of 1971 there were no known examples. Up to date, is this possibly true? Naively it seems impossible. In the spirit of Lefschetz fibrations, we have M_0 as a critical level set amongst the M_t (thinking of cylinders which get pinched via a vanishing cycle). It is then not generic, and any perturbation of this fiber (locally about the nodal point) would alter the topology. So to me

the inverted family $\lbrace N_t\rbrace$ couldn't exist, because it would force a generic M_{t_0} to take over the role as the critical level set amongst the N_t, but there is nothing "non-regular" about it. If the manifolds are allowed to be noncompact, perhaps it's easy, again via a rough sketch: take $\lbrace M_t\rbrace$ to be the family of open cylinders which pinch the vanishing cycles at $t=0$, and $\lbrace N_t\rbrace$ to be the family of "pinched" cylinders where the pinching point pushes off to infinity as $|t|\to 0$. Edit: The problem is more subtle than I thought, and my example with Lefschetz fibrations doesn't apply. From the definition of a "complex analytic family", all M_t are diffeomorphic to each other (in particular, they're all nonsingular spaces), and so we can only distinguish them by their holomorphic structures. In other words, $M_0\ne N_0$ means diffeomorphic but not complex-analytically homeomorphic.

Reduction argument from a general vertex set V(G) to a prime power in Prof. Keevash's proof on the Existence of Designs

The proof flow of the paper "On the Existence of Designs" by Prof. Keevash as I understand it is the following: -- Reduction from the general case to $V = \mathbb{F}_{p^a}$ (Lemma 6.3) -- Covering all the linearly dependent r-sets of $V = \mathbb{F}_{p^a}$ using Φ'. This also covers "bounded" number of r-sets which have linearly independent entries(dimension r over $\mathbb{F}_{p}$)but does not cover any set from the template G_r^{*}. -- Cover the r-sets of the template G_r^* using $M(G^*)$. The template is algebraically defined and it basically is a refined version of all q-tuples of the form My where the $q\times r$ matrix M has all the sub matrices of size r to be full rank and $y \in \mathbb{F}_{p^a}^r$. -- Now cover the r-sets that are full rank, not in the template G_r^* and not covered by Φ' using the nibble. -- Now to cover the r-sets that are not covered by the nibble, edges are picked from G_q (such that all r-sets except one belongs to G_r^*) in a greedy way randomly. This uses the processes defined in section 4 and generalised in section 5. This could cover few r-sets from the template G_r^* again. -- Express the sets of G_r^* that are covered twice as the difference $\partial\Psi^+ - \partial\Psi^-$. This uses Lemma 5.28 which is a generalisation of Graver and Zurkat's result. -- Apply local modifications on the covering of the template $M(G^*)$ to include $\partial\Psi^+$. This does not change G_r^*. This uses the cascade machinery built in the last subsection of section 5. -- Replace $\partial\Psi^+$ with $\partial\Psi^-$ in the template cover and this completes the construction. I was trying to understand the reduction as mentioned in the first step (Lemma 6.3). I do understand the way the complex is decomposed according to the intersection pattern with the set V' but I find myself stuck in the technicalities of the part where he proves that the greedy algorithm can always be completed(Page 46 last 2 paragraphs). The exact places at which I am not very clear are: 1) The motivation for keeping track of the full sets in the reduction argument to p^a. (Lemma 6.3). I am not very sure as to where exactly this is used but I think this is used in getting the degree regularity requirements to apply the nibble on A^x when $x^0 < r$. However I do understand why full sets were needed to be kept track of in the initial elimination of the dependent sets after the reduction to p^a in the proof of Theorem 6.1(Page 48). 2) Also I am not very clear on the analysis of G^2 in the proof of Lemma 6.3(page 46). Where he analyses G^2 by repeatedly restricting to a random subset (p-binomial) and a bounded subset (ie using Lemma 3.19 repeatedly). Could you please provide an intuitive explanation as to why the greedy algorithm here can be completed.

Long paths in the supercritical percolation.

I have a question on the length of the longest path, denoted by ℓ_n, in the supercritical percolation on $[0,n]^d$, denoted by C_n. We know that C_n has a giant component whose size is of order n^d. The question is that what is the order of ℓ_n. Is it n^d? For $d=2$, Grimmett proved that ℓ_n is of order n^2. The idea is interesting. He showed that there are many (of order n) edge-disjoint paths crossing the square from the left side to the right side. Then near the left and right sides, we can find crossings from the bottom to the top. By geometry property of the dimension 2, the two crossings cut all above edge-disjoint paths. Hence we get a long path whose size is of order n^2. For $d\geq 3$, it is shown that there are many (of order n^{d-1}) edge-disjoint paths crossing the square from the left side to the right side. However, I can not glue these paths. Do you have any idea to deal with my problem? Thank you in advance!

Is every projective space curve a set-theoretic intersection of two surfaces? What is known about this question?

I am sorry if this question has been already asked, couldn't find anything similar myself. I have recently recalled this long standing open problem of whether every irreducible curve in $\mathbb{P}^3(\mathbb{C})$ is a set-theoretic intersection of two surfaces in $\mathbb{P}^3(\mathbb{C})$. I know that there are results in characteristic $p > 0$. My question is what is the best result regarding this problem known today? Some references would be appreciated.

Ruth-Aaron triples, etc

A Ruth-Aaron pair is two numbers $(n,n+1)$ such that their sum of prime factors is equal, counting repeated prime factors. (The name refers to Hank Aaron's 715 homeruns surpassing Babe Ruth's 714!) So $$15 = 3 \cdot 5 \;;\; 3+5 = 8$$ $$16 = 2^4 \;;\; 2+2+2+2 = 2 \cdot 4 = 8$$ The notion can be generalized: $$417,162 = 2 \cdot 3 \cdot 251 \cdot 277 \;;\; 2+3+251+277 = 533$$ $$417,163 = 17 \cdot 53 \cdot 463 \;;\; 17+53+463 = 533$$ $$417,164 = 2^2 \cdot 11 \cdot 19 \cdot 499 \;;\; 2+2+11+19+499 = 533$$ My question is: Q. Are there k-tuples, for all $k \ge 2$, for which there exists at least one n such that $(n, n+1, n+2, \ldots, n+k)$ has the same sum of prime factors (counting repeated prime factors as above)? Addendum. I was out of date, relying on a "claimed proof by Erdős" that there were an infinite number of R-A pairs, which turned out not to be sound, as Benjamin Dickman explained. So the problem is open even for pairs, let alone k-tuples. Apparently no Ruth-Aaron quadruple is known. David Stork wrote Mathematica search code and found there are no such quadruples up to 10^{10}.

Open problems in Berkovich geometry

I would like to know if there is a state of the art recent reference on non-archimedean analytic spaces mentioning/listing open problems, conjectures, unresolved questions in the theory (*). I have looked for such a reference a bit, but didn't find anything. In case there is really nothing, I would be glad if experts in the field present here could enlighten me. (*) By "theory" I mean "mainstream" theory over a non-archimedean complete valued field (trivial valuations are accepted), including cohomological questions concerning the spaces themselves, but also theory over Banach rings, as mentioned in Berkovich's AMS monogograph. I must precise that even if dynamics and potential theory do perfectly fit for an answer, they are not my first target of interest, I am indeed looking for open problems, conjectures, unresolved or partially resolved questions that are more linked to Berkovich's or Temkin's works, that is, to works developing the theory or its links with schemes and formal schemes, cohomology, vanishing cycles.

Is a smooth closed surface in Euclidean 3-space rigid?

Classical theorem of Cohn-Vossen: A closed convex surface in Euclidean 3-space cannot be deformed isometrically. Robert Connelly found an example of a polyhedral surface that can be deformed isometrically. A metal hinged model of it can be found at IHES. But what about an arbitrary not-necessarily-convex smooth closed surface? Is it necessarily rigid? Or maybe it might be possible to make a smooth version of Connelly's example? It's easy to make smooth "hinges". The real challenge is finding a smooth model of the vertices, which is where two or more hinges meet.

On Descartes / spoof odd perfect numbers

Descartes, Frenicle, and subsequently Sorli, conjectured that $k = 1$, if $N = {q^k}{n^2}$ is an odd perfect number given in Eulerian form (i.e., q is prime with $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$). The inequality $q^k < n^2$ follows from a result of Pomerance. In particular, this implies that $n < q \Longrightarrow k = 1$ is true. (Note that, if $n < q$, then the Euler prime q becomes the largest prime factor of the odd perfect number N. In comparison to the case of even perfect numbers, the Mersenne prime $2^p - 1$ is the largest prime factor with exponent 1.) Taking off from a recent MO question, we have the following related papers: Descartes Numbers by Banks, et.al. and SPOOF ODD PERFECT NUMBERS by Dittmer My question is this: Does anybody here know of more recent papers that tackle whether the quasi-Euler prime of a spoof odd perfect / Descartes number is the largest quasi-prime factor and also has exponent 1? Quick searches via Google for the keywords "Descartes number" or "spoof odd perfect number" do not seem to yield much results. I have likewise e-mailed Professors Banks and Dittmer, hoping to get some information. [Edit (March 5, 2015): Just for the sake of comparison - In OEIS sequence A228059, T. D. Noe lists odd numbers of the form ${r^s}{t^2}$, where r is prime with $r \equiv s \equiv 1 \pmod 4$ and $\gcd(r,t)=1$, that are closer to being perfect than previous terms. He notes that, coincidentally the first 9 numbers in this sequence have the

exponent $s=1$. Additionally, except for the first number in the sequence (45), all of the succeeding numbers listed in A228059 satisfy $r < t$.]

What is the status on questions related to Bhargava's factorial function?

In Manjul Bhargava's The Factorial Function and Generalizations he motivates a new type of factorial $n!_S$ using by generalizing a few theorems like: For $k, l \in \mathbb{Z}$, we have $k! \times l!$ divides $(k+l)!$. For any primitive polynomial $f(x) \in \mathbb{Z}[x]$ with $\deg f = k$ then $\mathrm{gcd}\{ f(a): a \in \mathbb{Z}\}$ divides $k!$ In the process of solving generalizing these two results, he invents a factorial for any set of integers $S \in \mathbb{Z}$. For any prime p, order the element of S by: choose $a_0 \in S$ find a_1 giving the smallest power of $(a_1 - a_0)$ find a_2 giving the smallest power of $(a_2 - a_0)(a_2 - a_1)$ ... find a_k giving the smallest power of $\prod_{i< k} (a_k - a_i)$ One could look for analogues of the gamma function, stirling's approximation, binomial theorem and taylor series expansion of e and indeed, Bhargava mentions these questions towards the end of the paper. Have any of these questions been answered (partially or otherwise)?

The open problem in General Relativity?

Q. Is there a single, clear mathematical question that has emerged as the open problem in General Relativity? I ask this on the ~100th anniversary of Einstein's (4-page!) 1915 paper, "Die Feldgleichungen der Gravitation," Preussische Akademie der Wissenschaften, Sitzungsberichte, 1915 (part 2), 844-847. (Wikisource:The Field Equations of Gravitation.) Einstein's notebook, Riemann curvature tensor. It is difficult to surpass Willie Wong's thorough 2011 answer to the MSE question, "Open problems in General Relativity." But perhaps a core mathematical question has risen to the fore since? Naked singularities? Beyond the Cauchy horizon? "Electrodynamics of moving bodies?" Florentin Smarandache's 2013 Unsolved Problems in Special and General Relativity (PDF download.)? Or perhaps Willie's inventory cannot be condensed or sorted further at this point in time?

distribution of degree of minimum polynomial for eigenvalues of random matrix with elements in finite field

This is an attempt to extend the current full fledged random matrix theory to fields of positive characteristics. So here is a possible setup for the problem: Let $A_{n,p}$ be an $n \times n$ matrix with entries iid taking values uniformly in F_p. Then one should be able to find its eigenvalues together with multiplicities, which might lie in some finite extension of the field F_p. To ensure diagonalizability, one might even take $A_{n,p}$ to be symmetric or antisymmetric (I am not so sure if that guarantees diagonalizability in F_p but I have no counterexamples either). Now the question is if we associate to each eigenvalue λ the degree of its minimal polynomial $d(\lambda)$, then does the distribution of $d(\lambda)$ as n goes to infinite converge to some law upon normalization (say maybe Gaussian)? I am very curious whether others have studied this problem before. Maybe it's completely trivial.

What are the strongest conjectured uniform versions of Serre's Open Image Theorem?

This question concerns the uniform conjectured effective versions and generalizations of these two results of Serre on ℓ-adic Galois representations $\rho_{E,\ell}$ associated to a non-CM elliptic curve E defined over a number field K: For each prime ℓ, the index $I(E,\ell)$ of the image of $\rho_{E,\ell}$ in $\operatorname{GL}_2(\mathbb{Z}_\ell)$ is finite (and bounded independent of ℓ), and The representation $\rho_{E,\ell}$ is surjective for all but finitely many primes ℓ. Remark: As I understand it, these two statements together say that the representation $\rho_E:G_K \to \operatorname{GL}_2(\hat{\mathbb{Z}})$ made up of all the ℓ-adic ones has open image, and hence "Serre's Open Image Theorem" refers to both of these statements, although many papers written on this topic seem to only discuss one statement or the other. Let $p_0(E)$ denote the smallest prime such that $\rho_{E,\ell}$ is surjective for all $\ell > p_0$. My question: What are the strongest conjectured ("conjectured" means either officially conjectured or in a folklore way, or even someone writing down that they hope it's true) generalizations of Serre's Theorem which are uniform in E? Here are examples of the kind of statements I am referring to: Conjecture 1: $p_0(E)$ is bounded independently of E, where E ranges over all elliptic curves defined over $\mathbb{Q}$ (and the bound is 37). Conjecture 2: $I(E,\ell)$ is bounded independently of E and ℓ, where E ranges over all elliptic curves defined over $\mathbb{Q}$ (and the bound is...?). Conjecture 1': Like Conjecture 1, but for elliptic curves defined over an arbitrary number field K, and the bound only depends on K. Conjecture 2': Like Conjecture 2, but for elliptic curves defined over an arbitrary number field K, and the bound only depends on K. Conjecture 1'': Like Conjecture 1', but the bound only depends on $[K:\mathbb{Q}]$. Conjecture 2'': Like Conjecture 2', but the bound only depends on $[K:\mathbb{Q}]$. I am aware that a lot of

progress has been made on Conjecture 1, and we might be close to knowing that one.

Open problems in Banach spaces, universality

I have gathered a list of universality problems in Banach spaces which have been solved: 1.The non existence of a separable reflexive space universal for the class of separable reflexive spaces. 2.If a space is universal for the class of separable reflexive spaces, then it is universal for the class of separable Banach spaces. 3.There is a separable reflexive space which is universal for all separable uniformly convex spaces. My question is, are there any open problems in a similar vein to these?

Arctangents of odd powers of the golden ratio

While trying to answer this MSE question, I found that arctangents of many odd powers of the golden ratio $\varphi=\frac{1+\sqrt5}2$ are expressible as rational linear combinations of arctangents of positive integers: $$\begin{align}
\arctan\varphi&=2\arctan1-\frac12\,\arctan2\\
\arctan\varphi^3&=\arctan1+\frac12\,\arctan2\\
\arctan\varphi^5&=4\arctan1-\frac32\,\arctan2\\
\arctan\varphi^7&=3\arctan1+\frac12\,\arctan2-\arctan5\\
\arctan\varphi^9&=\arctan1-\frac12\,\arctan2+\arctan4\\
\arctan\varphi^{11}&=5\arctan1+\frac12\,\arctan2-\arctan5-\arctan34\\
\arctan\varphi^{13}&=3\arctan1-\frac12\,\arctan2+\arctan4-\arctan89\\
\arctan\varphi^{15}&=-2\arctan1+\frac32\,\arctan2+\arctan11 \end{align}$$ I was not able to find such a representation for $\arctan\varphi^{17}$ though. Question 1. Can we prove that it does not exist? I also could not find such a representation for any positive even power. Question 2. Can we prove that it does not exist for any positive even power? Question 3. Is there a simple way to determine if such a representation exists for a given power?

Connes Embedding Conjecture and Fusion Categories

I was recently introduced to Connes' Embedding Conjecture (CEC) which states: Every separable type II_{1} factor is embeddable into R^{ω}. Where ω is a generic free ultrafilter on $\mathbb{N}$, R is a hyperfinite type II_{1} factor, and R^{ω} is the ultrapower of R with respect to ω. I'm not well versed in the theory of factors and this conjecture is mysterious and difficult for me to understand. However, there do seem to be a lot of equivalent formulations of CEC. For some examples of

this see: N. Ozawa, "About the Connes Embedding Conjecture---Algebraic Approaches---, arXiv:1212.1700 [math.QA] My background is in fusion categories, and given the relationship between subfactors and fusion categories I was led to wonder: Question: Are there statements in the theory of fusion categories that are equivalent to CEC, or does CEC have implications for fusion categories? My understanding of the connections between fusion categories and subfactors, I'm sorry to say, is quite weak. So it very well could be that there is simply no relation between CEC and fusion categories, which would be a completely acceptable answer.

Conjectured new primality test for Mersenne numbers

How to prove that this conjecture about a new primality test for Mersenne numbers is true ? Definition: Let $M_{q}=2^{q}-1 , S_{0} = 3^{2} + 1/3^{2} , \ and: \ S_{i+1} = S_{i}^{2}-2 \pmod{M_{q}}$ Conjecture: $$M_{q}\text{ is a prime iff: } \ S_{q-1} \equiv S_{0} \pmod{M_{q}}$$ $$\text{ and iff: } \prod_{0}^{q-2} S_i \equiv 1 \pmod{M_{q}}$$ $$\text{ and iff: } S_i \not\equiv S_0 \pmod{M_{q}} , 0 < i < q-1$$ The easy part part (if M_{q} is prime then $S_{q-1}\equiv S_{0} \pmod{M_{q}}$), has already been proven. See: http://tony.reix.free.fr/Mersenne/ConjectureLLTCyclesMersenne.pdf . Now, a proof of the converse is needed. The "classic" LLT by Lucas and Lehmer for Mersenne numbers is based on the binary tree of the digraph (under $x^2-2 \pmod{M_q}$). This new conjectured test makes use of a cycle of the same digraph. The goal of this question is to validate (or not) the method (use a cycle of the digraph) for Wagstaff numbers ($\dfrac{2^q+1}{3}$, q prime) for which we also lack a proof for the converse. See: https://trex58.files.wordpress.com/2009/01/wagstaffandfermat.pdf for a proof of the easy part, by Robert Gerbicz . I and a team (Vincent and Paul) had found a very large Wagstaff PRP with this algorithm. See: http://www.primenumbers.net/prptop/prptop.php (2^4031399+1)/3 , rank 9 for now.

Functions on [0,1] with positive fractional series coefficients and symmetric under x->1-x

Suppose a function $g(x)$ has a convergent power series expansion with real (not necessarily integer or rational) exponents on $[0,1]$ of the form $$ g(x)=\frac{1}{x^\delta}(1+\sum_{i=1}^\infty c_i x^{\Delta_i}) $$ where $\delta>0$, $0<\Delta_1<\Delta_2<\ldots$ and, crucially, $c_i>0$. Suppose further that $$ g(x)=g(1-x) $$ What is known about such functions? Do they occur anywhere in mathematics? (They do occur in theoretical physics, namely in the study of conformal field theories. In fact this condition is a toy model for operator product expansion associativity.) I can use the Hardy-Littlewood tauberian theorem to show that c_i's should have a certain asymptotic behavior. But this does not use the full strength of the condition $g(x)=g(1-x)$. Can I learn more about the asymptotics, e.g. about the subleading terms, via a smart use of this condition? I'm also interested in questions which are not asymptotic. E.g. I am interested how large Δ_1 can be for a fixed δ. Expanding around $x=1/2$ to third order I can easily show that $\Delta_1\le 2\delta+3$. I know that this bound is not best possible, since expanding to higher order and doing some numerics I can somewhat improve it. I'm interested in the exact bound on Δ_1 as a function of δ and which functions $g(x)$ saturate it. I can also study the question for δ integer under an extra assumption that all Δ_i's are integers. E.g. for $\delta=1$ I can find a function for which $\Delta_1= 3$: $$ g(x)=\frac{P(x)+P(1-x)}{2x(1-x)}=x^{-1}(1+2x^3+x^4+x^5+\ldots) $$ where $P(x)=3x^2-x^4$. I can also show that $\Delta_1= 4$ is impossible. But I'm most interested in the case when δ and Δ_i's are real.

Sets not containing the vertices of unit triangles (Question posed by Erdős)

Following this post, I have been thinking about the problem posed by Erdős, Does there exist a constant $c > 0$ such that every subset A of the plane of area more than c contains the vertices of a triangle of unit area? I think the spirit of the problem justifies assuming A is measurable (counterexamples exist for non-measurable sets, see post), and so we can use the following to simplify: If A is measurable, with finite measure a, then for every $\epsilon >0$ there exists an $n \in \mathbb{N},$ $r > 0,$ such that A can be filled with n non-overlapping disks of radius r with combined area $a' = n \pi r^2 > a(\eta_h -\epsilon)$, where $\eta_h \approx 0.9$ is the optimal packing density of disks in the plane. So we can reduce to just considering sets of nonoverlapping disks of equal radius r. The problem becomes, Does there exist a constant $c > 0$ such that every set A of n disks of radius r, with $n \pi r^2 > c$, contains the vertices of a triangle of unit area? Now, we can scale such a set A by $1/r$ (that is, probably expanding it, because probably $r < 1$.) and ask of the new set of n unit disks, if $n\pi r^2>c$, for some c, must A contain the vertices of a triangle of area $1/r^2$? Defining $\ell = c/{(\pi r^2)}$, if $\ell<n$, must A contain the vertices of a triangle of area $\pi \ell/c$? That is, must A contain vertices of triangles of all areas $< \pi n/c$? So, setting $c' = c/\pi$ (to get rid of the constant), we get the equivalent question, Does there exist a constant $c' > 0$ such that every set of n unit disks in the plane must contain the vertices of triangles of all areas $< n/c'$? Say we are given some such c', and we must determine the conditions under which a triangle of area $c < c'$ must have vertices in A. Now, since two unit disks with centers a distance $> n/c$ apart always contain the vertices of a triangle of area n/c, we can assume that these disks are all within a distance of n/c of each other. Thus, they all lie in a big disk D of radius $\frac{2n}{\sqrt{3}c}+2$, and area d_c. We can then look at pairs of points within this disk that must not both lie in A. That is, pairs of points in D which, together with some point in A, form the vertices of a triangle of area n/c. We denote this set $\mathcal{F}_2$. Using the usual product measure, we denote the measure of $\mathcal{F}_2 \in D \times D$, m_2. The measure of $D \times D$ itself is d_c^2. We can show that, m_2 = $\Omega(cd_c^2/\sum_{1 \leq i \leq j \leq n} {s_{ij}})$ as a function of c and n, where s_{ij} is the distance between the centers of the i^th and j^th disks. Letting $S = \sum_{1 \leq i \leq j \leq n} {s_{ij}}$, we win if $S = o(c)$ (S a function of both c and n). Now, we can also look at the set of individual points in D that are "forbidden," i.e., together with two points from A, form a triangle of area n/c. We denote this set $\mathcal{F}_1$, and take it as a subset of D, with measure denoted m_1. It can be shown that the set of points f_{ij} that are forbidden due to forming a triangle of area n/c with points in disks i and j, which we say has measure $m_{1,ij}$, satisfies, $m_{1,ij} = \Omega(d_c/s_{ij})$ $\mathcal{F}_1$ is the union of the f_{ij}. Naïvely summing the $m_{1,ij}$, we get the sum m_1' of their measures is, $m_1' = \Omega(d_cS)$. If this were indeed $\mathcal{F}_2$, we would win if $S \neq o(c)$, since $d_c \sim \frac{2n}{\sqrt{3}c}$ (winning meaning $m_1 > d_c$, a contradiction). Since, from before, if $S = o(c)$ we also win, the problem would be finished. You could simply pick c large enough, and either $\mathcal{F}_1$ or $\mathcal{F}_2$ would exceed the measure of its superset, a contradiction. But of course the area of a union is not the sum of the areas. And I can't find a way to deal with the intersections of the $m_{1,ij}$. I also can't tell if I'm really right next to a solution, or if I'm just hitting the brick wall surrounding the problem in a different spot. I hope you found this interesting, at least. If the way I put growth rates is too confusing, I'll post some updates to clarify. If you have any ideas, please let me know.

A conjecture associated with n-gon cut curve of degree m

This conjecture is a generalization of A theorem for cubic-A generalization of Carnot theorem, in MSE question. I'm an electrical engineer, I am not a mathematician. I don't know how to prove this result. Let $A_1A_2....A_n$ be a n-gons, Let m points B_{ij} lie on A_iA_{i+1} for j=1, 2,...., m. Then $m.n$ points B_{ij} for $i=1, 2, 3,...., n$ and $j=1, 2,...., m$ lie on a curve of degree m if only if: $$\prod_{i=1}^n \prod_{j=1}^m \frac{\overline{B_{ij}A_i}}{\overline{B_{ij}A_{i+1}}}=1$$ Note that: $A_{m+1}=A_1$

Bang's open question strengthening Tarski's planks problem

Tarski's Planks problem, solved by Thøger Bang in 1951, says (in a simplified $\mathbb{R}^2$ version) that it requires "planks" (parallel strips) of total width $\ge d$ in order to completely cover a disk of diameter d. The last paragraph of Bang's short paper poses an open problem: (Snapshot from Bang's paper.) Does anyone know if this problem has been solved? I am especially interested in $\mathbb{R}^2$. Bang, Thøger (1951), "A solution of the 'plank problem'", Proc. Amer. Math. Soc. 2 (6): 990-993, doi:10.2307/2031721, JSTOR 2031721, MR 0046672.

Gerstenhaber conjecture for free loop space

I- Is the following statement still a conjecture see this article ? Conjecture (?) Let M be a simply connected compact oriented d-manifold (smooth), then $HH^{\ast}(C^{\ast}(M))$ the Hochschild cohomology of cochain complexes associated to M is isomorphic as a Gerstenhaber algebra to $H_{\ast+d}(LM)$ the d-shifted homology of the free loop space on M. II- What are the recent advances in solving the conjecture ? III- Is there a short proof of the following fact: $HH^{\ast}(C^{\ast}(M))$ is isomorphic to $H_{\ast+d}(LM)$ as a graded vector space ?

Progress in Guy's "Unsolved problems in Number Theory"?

I often peruse through Guy's book whenever I'm not being boggled down by my research. It crossed my mind today if any of these "unsolved problems" have become indeed solved. I thought about doing a literature review to find out, but I realised that posting this question here is a much more a efficient way of finding the current status of these problems. I'm also open to finding out about any recent breakthroughs concerning said problems.

Can N^2 have only digits 0 and 1, other than $N=10^k$?

Pablo Solis asked this at a recent 20 questions seminar at Berkeley. Is there a positive integer N, not of the form 10^k, such that the digits of N^2 are all 0's and 1's? It seems very unlikely, but I don't have a proof. It's easy to see that such a number must end in 1 or 9, and then easy to see that it must end in 01, 49, 51 or 99, and you can continue recursively for as long as you like, determining possible "suffixes". Using this, I had a computer check for me that there are no such N up to about 10^{24}. If you pretend that the digits of N^2 are randomly distributed, and N has n-digits, there's a $(2/10)^{2n}$ chance of satisfying this condition. There are only 10^n n-digit numbers, so you might expect a $(4/10)^n$ chance of having a some n-digit number. This suggests we shouldn't expect to find anything. (If you try the same problem in other bases, where the probabilities are better, you do find a few: in base 5, 222112144, 22222111221444 and 100024441003001 work.)

A conjecture about $\lfloor n!\cdot q/e\rfloor-\,!n\cdot q$

I was thinking about this question asked at Math.SE, when I came up with the following conjecture. For every $q\in\mathbb Q$ consider a sequence $s_n^{(q)}$ (terms within the sequence are indexed by $n\in\mathbb N$): $$s_n^{(q)}=\left\lfloor\frac{n!\cdot q}{e}\right\rfloor-\,!n\cdot q$$ ($!n$ denotes the subfactorial). Conjecture: For every q the sequence $s_n^{(q)}$ is periodic. Furthemore, if q is a positive integer is a reciprocal of a positive integer m, then the period is: $$p_{1/m}=\begin{cases}m,\quad m\text{ is even}\\2m,\quad m\text{ is odd}\end{cases}$$ Could you suggest any ideas how to prove this conjecture?

Looking for (information about) long diamonds

I was given an open problem as a birthday present recently. While I can probably handle spoilers at this point, what I really want are literature and other references. Also acceptable would be suggestions for approaches. Ideally, search terms for the web are most welcome. (It is my lack of imagination for search terms for this problem that is most keeping me from doing preliminary research on it.) Question: Where and how can I find out more about the Problem ($C_p \lt 2$?) below? Problem: Let n be a an integer parameter sufficiently large. Let x and y be vectors in n-dimensional real space. (Do complex if it makes it easier.) We will be using a family of L_p norms $|z|$ for p real and greater than 1 (pth root of the sum of the pth powers of the n coordinates of the vector z), although other norms are also of interest. Fixing p and its associated norm, there is a value C_p (which may be independent of n and all other parameters) such that for all x and y with $|x|=|y|=|x-y|=1$, one has $|x+y|\leq C_p$. The triangle inequality gives $C_p \leq 2$, and for $p=2$ we have $C_2 = \sqrt{3}$. Is it true that $C_p \lt 2$? (Can we also hope that lim sup over all $p \gt 1$ of C_p is also less than 2?) C_p to me represents the length of the long diagonal of a rhombus (diamond) with short diagonal and sides length 1. Please retag this post as appropriate. All compact surfaces $S\subseteq \mathbb{R}^3$ are rigid?

Recently I've come across a lecture in differential geometry by Fernando Codá (in portuguese!) in which he stated that the following problem is (at least, up to 2014) open: Given $S\subseteq\mathbb{R}^3$ a smooth (i.e. C^∞) compact boundaryless connected surface (therefore orientable), let $f:S\times[0,1]\to \mathbb{R}^3$ be a differentiable map with $S_t:=f(S\times\{t\})$ being a surface and $f_t:S\to S_t$ an isometry (where $f_t(p):=f(p,t)$), where $f_0\equiv \mathrm{Id}_S$. Then there are rigid motions $A_t:\mathbb{R}^3\to\mathbb{R}^3$ with $f_t(S) = A_t(S)$. More generally, in the cases of the sphere S^2 (Liebmann's Theorem) and "ovaloids", i.e. surfaces with Gaussian curvature K strictly positive (Cohn-Vossen's rigidity theorem), it is known that isometric embeddings of it in $\mathbb{R}^3$ are exactly the restrictions of the rigid motions from $\mathbb{R}^3$. Not all compact connected surfaces $S\subseteq\mathbb{R}^3$ satisfies this, as pointed out in the book Curves and Surfaces, by S. Montiel and A. Ros: Anyway, it is possible to show that this isometry in particular cannot be obtained by a continuous family of isometries from the identity map to the latter, so it's not a counterexample to the conjecture. Although this seems to me to be a very studied problem, and I imagine that there must be several approachs to it, I just couldn't find enough information about it on the internet (the Montiel & Ros book was recommended by Codá later in the same lecture linked above), for "rigidity" seems to be a very comprehensive term. So my actual question is: Actual question: Where can I find more information about this problem and the current approaches going on?

A conjecture based on Wilson's theorem

Definitions: Lagrange's theorem implies that for each prime p, the factors of $(p - 1)!$ can be arranged in unequal pairs, with the exception of $±1$, where the product of each pair $≡ 1 \pmod p$. See Wiki article on Wilson's theorem. From the example in the link above, for $p=11$ we have $$(11-1)!=[(1\cdot10)]\cdot[(2\cdot6)(3\cdot4)(5\cdot9)(7\cdot8)] \equiv [-1]\cdot[1\cdot1\cdot1\cdot1] \equiv -1 \pmod{11}$$ Let the products of the pairs that $≡ 1 \pmod p$ be the multiset A_p, and A_{p_n} the multiset for the nth prime. For the above example then, $A_{p_5}=\{(2\cdot6),(3\cdot4),(5\cdot9),(7\cdot8)\}=\{12,12,45,56\}$. Conjecture: $$\lim\limits_{n\rightarrow\infty}\dfrac{\sum\limits_{k \in A_{p_n}}(k-1)}{(p_n)^3}\approx\frac18$$ where p_n is the nth prime. Examples: For $p=11$ we have $$\dfrac{11+11+44+55}{11^3}=\dfrac{1}{11}$$ For $p=997$ we have $$\dfrac{123218233}{997^3}=\dfrac{123218233}{991026973}$$ Comments: As @YCor noted below, the -1 in the $k-1$ can be removed, since its contribution tends to 0. The conjecture can therefore be simplified to $$\lim\limits_{n\rightarrow\infty}\dfrac{\sum\limits_{k \in A_{p_n}}k}{(p_n)^3}\approx\frac18$$ I have no idea whether the above statement is correct, or how to go about trying to find a proof. Any comments on the any of the above are most welcome.

On cubic reciprocity for $x^3+y^3+z^3 = 996$?

I. The Diophantine equation, $$x^3+y^3+z^3 = 3w^3\tag1$$ with $x\geq y \geq z$ and $w=1$ has only two known solutions, namely $1,1,1$ and $4,4,-5$. Are there larger ones? As Noam Elkies points out in this post, Cassels in a 1985 paper showed that $w=1$ must have, $$x\equiv y\equiv z \bmod 9\tag2$$ For general w, Heath-Brown in a 1992 paper showed that, $$\text{either}\;x\equiv y\equiv z \bmod 9,\; \text{or one of}\; x,y,z\;\text{is}\;9m\tag3$$ Checking the Elsenhans-Jahnel list for $x^3+y^3+z^3=N$ with $N<1000$, one finds large solutions for $w=2,3,4$. (The list only covers 10^{14}, so if it can be raised higher, maybe a large one can be found for $w=1$ as well.) II. Trying to find something similar to (1), and if I did my search right, there are at least two other N that obeyed (2), namely $N=996$, $$x^3+y^3+z^3 = 996\tag4$$ with, $$x,y,z = 11,2,\,-7$$ $$x,y,z = 2169364505441,\, -631266388780,\, -2151398424325$$ and $N = 2^4\times3^3+3=435$, $$x^3+y^3+z^3 = 435\tag5$$ with seven known (and rather large) solutions, all of which satisfied (2). Questions: Is it true that all x,y,z of (4) and (5) also obey $x\equiv y\equiv z \bmod 9$? In general, for what N does this condition hold?

Diagonal argument for even perfect numbers

Following this, let's define the notion of perfect sequence as follows: $(u_{i})_{i}$ is a perfect sequence if and only if it is the sequence of divisors of an even perfect number in increasing order or the infinite sequence $(u_{i})_{i}, \ \ u_{i}=2^{-i}$. Let's now list the set of finite perfect sequences by increasing number of terms, so that $(v_{1,i})=(1, 2, 3, 6)$, $(v_{2,i})=(1, 2, 4, 7, 14, 28)$, And so on. My question is: is the diagonal sequence $(v_{i,i})_{i}$ such that $\sum_{i}{v_{i,i}}^{-1}=2$? Many thanks in advance.

Open Problems for Undergraduates

Suppose: I am a 'problem-solver' rather than a 'theory-builder' I am an undergraduate student I have a passion for solving mathematical problems The homework I get is not satisfying (in the sense that the problems are computing-problems rather than problems that require creative thinking), and I get far too little homework Where can I find interesting problems (that require creative thinking) if I want to have fun solving mathematical problems and to practice problem-solving? Are there lists/books of such problems? Furthermore, suppose I want to know how it is to do research. Are there lists of the kind "open problems which can be understood by undergraduates". I guess these open problems should be in the fields of "discrete mathematics/combinatorics" and "graph theory". I only found: http://dimacs.rutgers.edu/~hochberg/undopen/

The complexity of Max-K interval selection

I came up with the following problem, but do not know how to analyze it. Let S be an ordered set of integers with size n (i.e., $S=\{1,2,...,n\}$). An interval $INV(a,b)$ covers the elements in S from a to b $(1 \leq a < b \leq n)$. For example, $INV(3,5)$ covers the element of $\{3,4,5\}$. Now I am trying to analyze the following problem: Given a set of intervals I, select k intervals R from I (i.e., $R\subseteq I$ and $|R|=k$), such that R covers the most of S. I am also interesting in a more generalized version where each element has a weight. But I wish to analyze the simpler version first. Specifically, I wish to know whether there exists polynomial time (wrt. n) for this problem. If not, is this problem NP-hard, and how to prove it ? Any hints or discussions would be very helpful. Thank you.

If $N = qn^2$ is an odd perfect number with $\gcd(q,n)=1$, is it possible to have $q + 1 = \sigma(n)$?

The title says it all. Question If $N = qn^2$ is an odd perfect number with Euler prime q and $\gcd(q,n)=1$, is it possible to have $q + 1 = \sigma(n)$? Heuristic From the Descartes spoof, with quasi-Euler prime q_1: $$n_1 = 3003 < \sigma(n_1) = 5376 < q_1 = 22021$$ So it appears that it might be possible to prove that $q + 1 \neq \sigma(n)$. Some Essential Estimates Acquaah and Konyagin recently obtained the estimate $q < n\sqrt{3}$. We will use this estimate to obtain an upper bound for $\sigma(q)/n$. Ochem and Rao recently obtained the lower bound $N > {10}^{1500}$ for the magnitude of an odd perfect number. Using this bound, together with the inequality $n < q$, gives $$I(q) < 1 + {10}^{-500}.$$ Motivation We wish to prove the following proposition: If $N = {q^k}{n^2}$ is an odd perfect number with Euler prime q, then $3 \nmid N$ implies that $q < n$. If $q + 1 \neq \sigma(n)$, then it follows that $$I(q) + I(n) \neq \frac{\sigma(q)}{n} + \frac{\sigma(n)}{q}$$ from which we obtain $$I(q) + I(n) < \frac{\sigma(q)}{n} + \frac{\sigma(n)}{q},$$ since the reverse inequality $$\frac{\sigma(q)}{n} + \frac{\sigma(n)}{q} < I(q) + I(n)$$ will violate the inequality $I(q) < \sqrt[3]{2} < I(n)$ (see this paper). (Edit February 8 2016: Assuming $$\frac{\sigma(q)}{n} + \frac{\sigma(n)}{q} < I(q) + I(n)$$ is true, then $$\left(q < n\right) \land \left(\sigma(n) < \sigma(q)\right)$$ is false. However, I am currently unable to rule out $$\left(n < q\right) \land \left(\sigma(q) < \sigma(n)\right).$$ This particular case remains open.) But the inequality $$I(q) + I(n) < \frac{\sigma(q)}{n} + \frac{\sigma(n)}{q}$$ implies that the biconditional $$q < n \Longleftrightarrow \sigma(q) < \sigma(n)$$ holds. This biconditional is then a key ingredient in the proof of the proposition mentioned earlier. My method is able to rule out $\sigma(q) = q + 1 = \sigma(n)$ if $3 \nmid n$, since we obtain $$2.799 \approx 1 + 2^{\frac{\log(6/5)}{\log(31/25)}} \leftarrow \frac{q + 1}{q} + \left(\frac{2q}{q + 1}\right)^{\frac{\log(I(5))}{\log(I(5^2))}} \leq I(q) + \left(I(n^2)\right)^{\frac{\log(I(u))}{\log(I(u^2))}}$$ $$< \frac{\sigma(q)}{q} + \frac{\sigma(n)}{n} = \frac{\sigma(q)}{n} + \frac{\sigma(q)}{q} < \sqrt{3}\left(1 + {10}^{-500}\right) + \left(1 + {10}^{-500}\right) \approx 2.732,$$ (where the smallest prime factor u of N satisfies $u \geq 5$), whence we arrive at a contradiction. Further Considerations If $\sigma(q) = q + 1 = \sigma(n)$ and $3 \mid n$, then the same method does not force a contradiction, because we then have $$2.7199 \approx 1 + 2^{\frac{\log(4/3)}{\log(13/9)}} \leftarrow \frac{q + 1}{q} + \left(\frac{2q}{q + 1}\right)^{\frac{\log(I(3))}{\log(I(3^2))}} \leq I(q) + \left(I(n^2)\right)^{\frac{\log(I(u))}{\log(I(u^2))}}$$ $$< \frac{\sigma(q)}{q} + \frac{\sigma(n)}{n} = \frac{\sigma(q)}{n} + \frac{\sigma(q)}{q} < \sqrt{3}\left(1 + {10}^{-500}\right) + \left(1 + {10}^{-500}\right) \approx 2.732,$$ where u is the smallest prime factor of N. Added February 7 2016 If $q + 1 = \sigma(n)$, then $\sigma(n) \equiv 2 \pmod 4$, so that n takes the form $$n = {p^r}{m^2}$$ where p is a prime with $p \equiv r \equiv 1 \pmod 4$ and $\gcd(p, m) = 1$. If $3 \mid n$, then $p \neq 3$, so that $3 \mid m$. So I have $$\sigma(n) = \sigma(p^r)\sigma(m^2)$$ where $\sigma(p^r) \equiv r + 1 \equiv 2 \pmod 4$. Since $\gcd(q, q+1) = 1$, then $\gcd(q, \sigma(n)) = 1$, so that $$\gcd(q, \sigma(p^r)\sigma(m^2)) = 1.$$ Thus, $q \nmid \sigma(p^r)$ and $q \nmid \sigma(m^2)$. However, note that $$q \mid \sigma(n^2) = \sigma(p^{2r})\sigma(m^4).$$ Alas here is where I get stuck.

Open problems in Hopf algebras

I couldn't find a list of open problems in Hopf algebras. So my question is the following: In the theory of Hopf algebras, what are the (big) open problems? Any kind of problem/question will be welcome. I am interested in any kind of problem involving Hopf algebras, say going from combinatorics or topology to abstract algebra.

A generalization of Frankl's conjecture?

Would it be reasonable to conjecture what follows : there is a real constant $c > 1/2$ such that, for every natural number n, if $X_{1}, \ldots , X_{n}$ is a union-stable family of distinct finite sets with at least two elements in their union U, then there is at least one subset of U with two elements that intersects at least $cn - 1$ sets X_{i} ? Thanks in advance.

Torsion-freeness of two groups with 2 generators and 3 relators and Kaplansky Zero Divisor Conjecture

Let G_1 and G_2 be the groups with the following presentations: $$G_1=\langle a,b \;|\; (ab)^2=a^{-1}ba^{-1}, (a^{-1}ba^{-1})^2=b^{-2}a, (ba^{-1})^2=a^{-2}b^2 \rangle,$$ $$G_2=\langle a,b \;|\; ab=(a^{-1}ba^{-1})^2, (b^{-1}ab^{-1})^2=a^{-2}b, (ba^{-1})^2=a^{-2}b^2 \rangle,$$ Are these groups torsion-free? Motivation: In both of these groups $1+a+b$ as an element of the group algebra $\mathbb{F}_2[G_i]$ over the field with two elements is a zero divisor. Thus one has a counterexample for the Kaplansky zero divisor conjecture if one of G_is is torsion-free! $$(1+a+b)(b^{-1}a^{-2}ba^{-1}+a^{-1}ba^{-2}ba^{-1}+a^{-1}ba^{-1}+b^{-1}a^{-1}+a^{-1}b^2a^{-1}ba^{-1}+aba^{-1}ba^{-1}+1+a^{-2}ba^{-1}+a^{-1}b^{-1}a^{-1}+b+baba^{-1}ba^{-1}+ba^{-1}ba^{-1}+a^{-1}+b^{-1}a)=0$$ $$(1+a+b)(aba^{-1}ba^{-1}+a^{-1}b^2a^{-1}ba^{-1}+a^{-1}ba^{-1}+b^{-1}a^{-1}+b^{-1}a^{-2}ba^{-1}+ab+1+ba^{-1}ba^{-1}+baba^{-1}ba^{-1}+b+bab+a^{-2 }ba^{-1}+a^{-1}+b^{-1}a)=0$$

Hamiltonian S^1 actions with isolated fixed points

I have in mind the following question for some time. Is there an example of a compact symplectic manifold with a Hamiltonian S^1-action with isolated fixed points, that does not admit a compatible S^1-invariant Kahler strucutre? One would say, of course there should be such an example. But I have not seen any... Added, 2009. Apparently this is an open problem. PS, 2019. Not anymore!

A cubic and six conics problem

I am an electrical engineer system. I live in Viet Nam. I am not a Mathematician. I construct and found a problem as follows: Let a cubic, and five conics (C_1), (C_2), (C_3), (C_4), (C_5). The Cubic and a conic (C_i) have six common points. Conic (C_i) and conic $(C_{i+1}$ and the cubic have three common points for $i=1,2,3,4$. Let P_1, P_2, P_3 lie on (C_1) and the cubic but don't lie on (C_2) and P_4, P_5, P_6 lie on (C_5) and cubic but don't lie on (C_4). Then $P_1, P_2, P_3, P_4, P_5, P_6$ lie on a conic. I need a proof? Could you help me give your proof?

A problem of four curves

This is a generalization of my previous question, a problem of a cubic and six conics. Let a curve (K) of degree m and three curves (C_i) of degree n, for $i=1,2,3$. Let (C_1) meets (K) at mn points. Let (C_2) meets (K) at mn points. Let (C_3) meets (K) at mn points. Let $(C_1), (C_2)$ and K have d common points. Let points $P_1, P_2, ...,P_{mn-d}$ lie on (C_1) and (K) but don’t lie on (C_2). Let $(C_2), (C_3)$ and K have $mn-d$ common points. Let points $Q_1, Q_2, Q_3,....,Q_d$ lie on C_3 and (K) but don’t lie on C_2. The problem: show that the mn points $P_1, P_2, ...,P_{mn-d}, Q_1, Q_2, Q_3,....,Q_d $ lie on a curve of degree n, where $mn-d < \frac{n^2+3n}{2}$ and $d < \frac{n^2+3n}{2}$. The first figure I, make with $m=3$, $n=2$ and $d=2, mn-d=4$ The second figure I, make with $m=4$, $n=2$ and $d=4, mn-d=4 $. In this case 8 points lie on a new conic. The third figure, I make with $m=4$, $n=3$ and $d=6, mn-d=12-6=6 $. In this case, I make curve C_1, C_2, C_3 = three cubics, one cubic = three line, the curve (K) = 4 line, the new curve is a conic through 8 points and a line share a same line of cubic 1.

When does the converse to Schur's Lemma hold?

Let R be a commutative ring, let A be an R-algebra, and let M be an A-module. If M is simple, then End$_{A-mod}(M)$ is a division ring. A common use is when R is the complex numbers $\mathbb{C}$, and M is such that End$_{A-mod}(M)$ is finite dimensional. Then End$_{A-mod}(M) = \mathbb{C}$. Under what circumstances (regarding R and/or A) is the converse true, that the endomorphism ring being a division ring, or being just R itself, implies that M is simple?

On even almost perfect numbers other than powers of two

(Note: This question is an improved version of and has been cross-posted from this MSE post.) Let $\sigma(x)$ denote the sum of the divisors of x. If $\sigma(x) = 2x - 1$, then we call x an almost perfect number. If b is an odd composite and $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = \sigma(2^r)$ with $r \geq 1$, then $M = {2^r}{b^2}$ is an even almost perfect number. Now, if $\sigma(2^r)$ is prime, then ${2^r}{\sigma(2^r)}$ is an even perfect number. In an answer to the linked MSE question, Giovanni Resta asserts that: If $b = 3^k$ for $k > 1$ then $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q = 2$. Up to ${10}^8$ there are no other values of b that make q prime. However, by work of Antalan, it is known that $3 \nmid b$, if $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = \sigma(2^r)$ with $r \geq 1$. Hence, I cannot help but ask: (1) Is it possible to prove that if b is an odd composite and $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q$ is prime, then necessarily $b = 3^k$ with $k > 1$? If it is not possible by current mathematical methods, what is the main obstruction? (2) If b is an odd composite and $r \geq 1$, is it possible to prove that $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} \neq \sigma(2^r)$? If it is not possible by current mathematical methods, what is the main obstruction?

A long-lasting conjecture of Pólya & Szegő

There is a conjecture by Pólya & Szegő (~1950, stated in p. 159 of their book Isoperimetric Inequalities in Mathematical Physics) which is as follows: "Of all n-gons of a fixed area, the regular n-gon minimizes the first Dirichlet eigenvalue." Surprisingly, this is still open (to my knowledge) for the general case. The only settled cases are the triangles and the quadrilaterals (see Henrot's survey). Is there any progress on the general case?

A conjecture of Blakley and Dixon about odd powers of positive matrices

In a 1966 paper Blakley and Dixon conjecture the following. Let S be a symmetric matrix with nonnegative entries and let u be a unit vector with nonnegative entries. For integers $k\ge j$ both odd, $$\langle u, S^ku\rangle^j\ge \langle u, S^ju\rangle^k.$$ They verify this conjecture under the condition that RHS is sufficiently large. I am wondering if there has been any progress towards this conjecture. A year earlier, Blakley and Roy verify the $j=1$ case. This also implies that the conjecture is true whenever j divides k. There are no papers known to Google scholar citing this paper that solves the conjecture.

In a Banach algebra, do ab and ba have almost the same exponential spectrum?

Let A be a complex Banach algebra with identity 1. Define the exponential spectrum $e(x)$ of an element $x\in A$ by $$e(x)= \{\lambda\in\mathbb{C}: x-\lambda1 \notin G_1(A)\},$$ where $G_1(A)$ is the connected component of the group of invertibles $G(A)$ that contains the identity. Is it true that $e(ab)\cup\{0\} = e(ba)\cup\{0\}$ for all $a,b \in A$? Equivalently, is it true that $1-ab$ is in $G_1(A)$ if and only if $1-ba$ is in $G_1(A)$, for all $a,b \in A$? Note: The usual spectrum has this property. Just an additional note: We have $e(ab)\cup\{0\} = e(ba)\cup\{0\}$ for all $a,b \in A$ if 1) The group of invertibles of A is connected, because then the exponential spectrum of any element is just the usual spectrum of that element. 2) The set $Z(A)G(A) = \{ab: a \in Z(A), b\in G(A)\}$ is dense in A, where $Z(A)$ is the center of A. (One can prove this). In particular, we have $e(ab)\cup\{0\} = e(ba)\cup\{0\}$ for all $a,b \in A$ if the invertibles are dense in A. 3) A is commutative, clearly. But what about other Banach algebras? Can someone provide a counterexample?

What explains the asymptotic and the pattern in this sequence related to Riemann zeta zeros?

As the starting point for my experiment I assumed that the imaginary parts of the Riemann zeta zeros are of the form: $$\Im \{ \rho_n \} = \frac{2\pi}{\log x_n}$$ where x_n is unknown. Therefore I solved for x_n and got this integer sequence: $$\Large a_1(n) = (n+1) \left(\left[\frac{1}{e^{\frac{2 \pi }{\Im(\rho _{n+1})}}-1}\right]-\left[\frac{1}{e^{\frac{2 \pi }{\Im(\rho _n)}}-1}\right]\right)$$ where $\left[\text{number}\right]$ is the round or nearest integer function. This is a sequence starting: $a_1 =\;$2, 3, 0, 5, 0, 7, 0, 9, 0, 11, 0, 13, 0, 15, 0, 17, 0, 19, 0, 0, 22, 0, 0, 25, 0, ... $ \; a_1(n)$ I then deleted the zeros in that sequence to get: $a_2 =\;$2, 3, 5, 7, 9, 11, 13, 15, 17, 19, 22, 25, 27, 30, 33, 36, 39, 42, 45, 48, 51, 54, 57, 61, 64,... Now a search in The On-Line Encyclopedia of Integer Sequences (OEIS) suggests that the first few terms are sequence A092919. Therefore the sequence: $$b(k)=\sum _{n=1}^{k+2} \text{Round}[\log (n)]$$ where k is a natural number: $$k=1,2,3,4,5,...$$ agrees with the beginning of $a_2 \;$. $b = \;$ 2, 3, 5, 7, 9, 11, 13, 15, 17, 19, 22, 25, 28, 31,... With Odlyzko's list of the 100000 first Riemann zeta zeros I plotted the difference $a_2 - b$: . . . The smoothness is only apparent at a such zoomed out plot. Actually when zooming in at the beginning it looks like this: Just for clarity I plotted the sequence a_2 and its conjectured asymptotic b separately also: Mathematica 8 code for the plots: (*start*) (*Mathematica 8*) nn = 1000; Monitor[a1 = Table[(n + 1)*(Round[(Exp[1/(Im[ZetaZero[n + 1]]/(2*Pi))] - 1)^-1] - Round[(Exp[1/(Im[ZetaZero[n]]/(2*Pi))] - 1)^-1]), {n, 1, nn}], n] a2 = DeleteCases[a1, 0] b = Table[Sum[Round[Log[n]], {n, 1, k}], {k, 3, Length[a2] + 2}] cc = a2 - b; cc[[1 ;; 20]] Label g1 = ListLinePlot[a2, PlotStyle -> Red, PlotLabel -> "sequence a2"] g2 = ListLinePlot[b, PlotLabel -> "asymptotic b"] g3 = Show[g1, g2, PlotLabel -> "sequence a2 and asymptotic b superimposed"] g4 = ListLinePlot[cc, PlotLabel -> "difference between sequence a2 and asymptotic b"] GraphicsGrid[{{g1, g2}, {g3, g4}}] (*end*) Is the sequence

b asymptotic to sequence a_2 and what explains the large scale repeating pattern in the difference $a_2 - b$?

Covers of Riemann surfaces which become arbitrary close in Teichmuller space

Suppose S and S' are two compact Riemann surfaces of genus g. Does there exist a sequence of genera $g_i \to \infty$ and covers S_i, S_{i}' of S,S', both of genus g_i, such that $d(S_i,S_{i}')\to 0$? Here d a "natural" distance function on Teichmuller space, of which I suppose there are many, but for definiteness let's take it to be induced by the Teichmuller metric. This question was asked to me by Rick Kenyon last year, and some brief thought on it got me nowhere.

Prove this conjecture inequality

This following problem is from my Conjecture many years ago, Question : Let $a,b>0,n\in N^{+},n\ge 3$,such $$a^n+b^n+(2n+2)(ab)^n\le 2n$$ Conjecture: then $a+b\le 2$ or $a+b>2.a>0.b>0,n\ge 3$,then we prove $$a^n+b^n+(2n+2)a^nb^n-2n>0$$ or it suffuce to prove $$a^n+b^n+(2n+2)a^nb^n-2n>0\rm{when}~ a+b=2$$ This inequality is from this conjecture $$\sqrt[n]{\dfrac{x}{1+y}}+\sqrt[n]{\dfrac{y}{1+x}}\le 2,\rm{where}~ x+y\le 2n,n\ge 3,n\in N^{+}$$ it is not hard to prove this case $n=3,4$,but for $n\ge 5$, use this $$\sqrt[n]{\dfrac{x}{1+y}}=a,\sqrt[n]{\dfrac{y}{1+x}}=b$$ then $$x=\dfrac{a^n(b^n+1)}{1-(ab)^n},y=\dfrac{b^n(a^n+1)}{1-(ab)^n}$$take $x+y\le 2n\Longrightarrow a^n+b^n+(2n+2)(ab)^n\le 2n$

Pro-V topology on a free group

Let $W=G_p*G_q$, where G_p and G_q are pseudovarieties of all finite p-groups and all finite q-groups respectively, with p and q fixed prime numbers. The pro-W topology on a group G is the unique group topology such that the set of normal subgroups N with G/N in W is a fundamental system of neighborhoods of the identity. Let $FG(A)$ be a finitely generated free group. Steinberg and Auinger proved that the pro-W closure of a finitely generated subgroup H of $FG(A)$ is also finitely generated. Question. Let H be a finitely generated subgroup of a finitely generated free group $FG(A)$. Is there an algorithm to compute a basis for the pro-W closure H given as input a generating set for H? We know that every minimal normal subgroup of a finite p-group G is isomorphic to $\mathbb{Z}_p$, hence G has a finite normal series $$1=N_1\leq N_2\leq \ldots N_m=G$$ such that $N_{i+1}/N_{i}\simeq \mathbb{Z}_p$. Hence, we can write $G_q=\bigcup_{i=1}^{\infty} V^i$ where V is the locally finite pseudovariety generated by $\mathbb{Z}_q$ and $V^i={V*V*\ldots*V}$. By Proposition 4.6 in "HALL VARIETIES OF FINITE SUPERSOLVABLE GROUPS", the G_p*V-closure of a finitely generated subgroup H of $FG(A)$ is computable. By induction on i, we can prove that the G_p*V^i- closure of H is computable. So, we have a chain $$Cl_{Gp*V}(H)\geq Cl_{Gp*V^2}(H)\geq\ldots\geq Cl_{Gp*V^n}(H)\geq \ldots $$ of subgroups of $FG(A)$ containing $Cl_{G_p*G_q}(H)$. By Theorem 7.5 and Theorem 5.14 in "the geometry of profinite graphs with applications to free groups and finite monoids", every pseudovariety G_p*V^i is Hall pseudovariety that means the automaton of $Cl_{G_p*V^i}(H)$ is a quotient of the automaton of H. Since H is a finitely generated subgroup, the automaton of H is finite and so, the chain must stop somewhere and therefore there is i such that $Cl_{G_p*G_q}(H)=Cl_{Gp*V^i}(H)$. But the question is "Is there any bounded on i?

Can we solve the FGF problem by finding an appropriate action?

If we can find an action of the free group $\mathbb{F}_2$ on a measure space X such that the crossed product $M=L^∞(X)⋊\mathbb{F}_2$ is a ${\rm III}_1$ factor with core isomorphic to $L(\mathbb{F}_2)⊗B(H)$, then the fundamental group of $L(\mathbb{F}_2)$ is $\mathbb{R}_+$, and the free group factors isomorphism problem is solved. Remark: There is an attempt here. Question: Can we rule out to solve this problem like that? Remark: One obstruction could be that M admits a Cartan subalgebra whereas $L(\mathbb{F}_2)$ not. To validate this obstruction, it is necessary to prove that the process of taking the core and to truncate it by a projection of trace 1, keeps the existence of a Cartan subalgebra. If we can rule out this method: Can we improve it by replacing $L^∞(X)$ by a more appropriate von Neumann algebra? More generally: Could we expect to be able to build by hand a ${\rm III}_1$ factor with core $L(\mathbb{F}_2)⊗B(H)$?

Is there an uncountable, non-discrete, Hausdorff Toronto space?

We call a topological space X a Toronto space if for any subspace $Y \subseteq X$ such that Y and X have the same cardinality it follows that Y is homeomorphic to X. Does anybody know what is known about the following question?: Is there an uncountable, non-discrete, Hausdorff Toronto space? It is not hard to show that if X is countable, Hausdorff and Toronto then X has the discrete topology. I have been thinking about the uncountable case for a while and it turns out it is a much harder question.

Current status of Bloch constant and Landau constant bounds

The Bloch constant B (based on a theorem introduced by André Bloch in 1925 on the maximum radius of a one-to-one disk in the image of a normalized analytic function of the unit disk, see for instance Remmert "Funktionentheorie II" or Steven Finch marvelous "Mathematical constants") was conjectured by Ahlfors to be $$ \frac{1}{\sqrt{1+\sqrt{3}}} \frac{\Gamma(\frac{1}{3})\Gamma(\frac{11}{12})}{\Gamma(\frac{1}{4})}$$ (This value, if I remember well Ahlfors' article corresponds to a particular function that he constructed for this purpose). The Bloch Constant B is currently known to be at least slightly greater than $\frac{\sqrt{3}}{4}$ (several articles improving upon each other by Mario Bonk, Chen and Gauthier, Xiong). Has there been some progress since 1998 on the lower bound ? Same question for the closely related (univalent) Landau constant (quite often called Bloch-Landau constant, sometimes seen as B_∞) ? The conjectured upper bound is $$\frac{\Gamma(\frac{1}{3})\Gamma(\frac{5}{6})}{\Gamma(\frac{1}{6})}$$ What can be said of the various adaptations or specializations of this constant to various class of functions, and extensions of these constants to several complex variables or other functional spaces ? I give as background the original article from Bloch, Ahlfors and Grunsky. (1) A. Bloch, Les théorèmes de M. Valiron sur les fonctions entières et la théorie de l'uniformisation, Ann. Fac. Sci. Univ. Toulouse, vol. 17, (1925), pp1-22. (2) L. V. Ahlfors and H. Grunsky, Über die Blochsche Konstante, Math. Zeitschrift 42 (1937), pp671-673. (3) L. V. Ahlfors, An extension of Schwarz's lemma, Trans. Amer. Math. Soc. 43 (1938), pp359-364. (these two are reprinted in Ahlfors Works vol 1) Ahlfors life and works are evocated in an [AMS Notices][1] of 1998.

If $N = q^k n^2$ is an odd perfect number, and $n < q^{k+1}$, does it follow that $k > 1$?

Let $N = q^k n^2$ be an odd perfect number with Euler prime q. According to Dickson (as pointed out recently by Beasley), Descartes conjectured $k=1$ in a letter to Mersenne in 1638, with Frenicle's subsequent observation occurring in 1657. In recent times, Sorli (page 89) conjectured that $k=1$ in his PhD thesis titled Algorithms in the study of multiperfect and odd perfect numbers. Following Brown's recent announcement of a proof for $q < n$, and a partial proof that $q^k < n$ holds under many cases, I recently realized that the biconditional $$q < n \iff \sigma(q) < \sigma(n) \iff \dfrac{\sigma(q)}{n} < \dfrac{\sigma(n)}{q}$$ would follow suit, if Brown's proof for $q < n$ is correct. (Similarly, $$q^k < n \iff \sigma(q^k) < \sigma(n) \iff \dfrac{\sigma(q^k)}{n} < \dfrac{\sigma(n)}{q^k}$$ would follow, if $q^k < n$ is true.) In this MSE post, I asked the following question (back in March 2014): If $N = q^k n^2$ is an odd perfect number, if $n < q^{k+1}$, does it follow that $k > 1$? Brown actually proves $q < n$ by proving $k = 1 \implies q < n$, so that we obtain that the implication $$k = 1 \implies \sigma(q) = \sigma(q^k) < n$$ holds, since $q < n < q+1 = \sigma(q)$ is impossible. By the contrapositive, $n < \sigma(q^k) \implies k > 1$. My question here is: To what extent can we then prove that $n < q^{k+1} \implies k > 1$? I note that $n < \sigma(q^k) \implies n < q^{k+1}$, but the converse may not necessarily be true. Notice that the implication $$n < q^{k+1} \implies k > 1$$ will prove that $$q^2 < n,$$ since it is known that $$n < q^2 \implies k = 1.$$

Cutting convex sets

Any bounded convex set of the Euclidean plane can be cut into two convex pieces of equal area and circumference. Can one cut every bounded convex set of the Euclidean plane into an arbitrary number n of convex pieces having equal area and circumference? The solution of this problem for $n=2$ is generically unique. Are there other values of n (assuming that the problem is possible) where this happens? More generally, given a $d-$dimensional bounded convex set C in the Euclidean space $\mathbf E^d$ of dimension d. for which values of n can one cut C into n convex pieces of equal area with boundaries of equal $(d-1)-$dimensional area? ($n=2$ is again easy, but the solution is no longer generically unique if $d>2$). Are there values for (n,d) for which the solution always exists in a generically unique way (or for which the number of solutions is generically finite)?

Primes and the factorial

Conjectures: For all prime numbers $p>5$ there exist a prime number $q<p$ such that $q\equiv m!\!\pmod p$, for some m with $2<m<p$. and For all primes p there is a prime $q<p^2$ such that $q\equiv m!\pmod {p^2}$, for some m with $2<m<p^2$. (Even $2<m<p$ as pointed out in comment). Both tested for all $p<100,000,000$. There are reasons to believe that the conjectures are true. If p is a large prime there are a lot of nonzero solutions to $n\equiv m!\!\pmod p$ and to $n\equiv m!\!\pmod {p^2}$. The probability for one of those n to be a prime increase with p. https://math.stackexchange.com/questions/1838931/conjecture-about-primes-and-the-factorial

An inequality in cyclic polygon and tangential polygon

I proposed my conjecture, it is strengthened version of the Erdős-Mordell inequality as following: Let $A_1A_2.....A_n$ be a cyclic polygon and $B_1B_2....B_n$ be the its tangential polygon. Let P be an arbitrary point inside of $A_1A_2.....A_n$. Let d_i be the distances from P to A_iA_{i+1}, for $i=1,...,n$ and $A_{i+1}=A_1$, and D_i be the distances from P to B_iB_{i+1}, for $i=1,...,n$ and $B_{i+1}=B_1$. Then show that: $$\sum_{1}^{n}{ D_i} \ge sec{\frac{\pi}{n}}\sum_{1}^{n}{d_i} $$ Equality holds when

$A_1A_2....A_n$ be the regular polygon. A proof of the case polygon is a triangle in the paper A strengthened version of the Erdős-Mordell inequality", Forum Geometricorum, 16: 317-321, MR 3556993. I am looking for a proof of general case.

A conjecture generalization of Karamata inequality

Fist I observe function $f(x)=x^2$ in the figure as following I found that when $x_1 \ge y_1$ and $x_2 \le y_2$ $\Rightarrow$ $AB \ge CD$ $\Rightarrow$ $$\frac{f(x_1)+f(x_2)}{2}-f(\frac{x_1+x_2}{2}) \ge \frac{f(y_1)+f(y_2)}{2}-f(\frac{y_1+y_2}{2})$$ (1). Note that: When $x_1+x_2=y_1+y_2$ the inequality (1) is Karamata inequality (with case n=2) $$f(x_1)+f(x_2) \ge f(y_1)+f(y_2)$$ From above observation, I am looking for a proof of a conjecture generalization of Karamata inequality as following: Let I be an interval of the real line and let f denote a real-valued, convex function defined on I. If $x_1, . . . , x_n$ and $y_1, . . . , y_n$ are numbers in I such that: $x_1 \ge x_2 \ge x_3...\ge x_n,$ and $y_1 \ge y_2 \ge y_3...\ge y_n$ 2.x_1+x_2+...+x_i \ge y_1+y_2+...+y_i for i=1,...,n-1 and 3. x_n \le y_n 2'. $x_1+...+x_i \ge y_1+...+y_i$ and $x_{i+1}+...+x_n \le y_{i+1}+...+y_n$ for $i=1,...,n-1$ then $$\frac{f(x_1)+f(x_2)+...+f(x_n)}{n}-f(\frac{x_1+x_2+...+x_n}{n}) \ge \frac{f(y_1)+f(y_2)+...+f(y_n)}{n}-f(\frac{y_1+y_2+...+y_n}{n}) $$ The inequality holds with equality if and only if $x_i=y_i$ for all $i \in {1, 2,...,n}$

Does every separable Banach space have a Markushevich-Auerbach basis?

Let X be a separable Banach space and X^* be its dual, let $\{x_i\}$ be a sequence in X with dense linear span and such that there exists a sequence $\{x_i^*\}$ in X^* satisfying $x_i^*(x_j)=\delta_{i,j}$ (Kronecker delta). It is clear that $\{x_i^*\}$ is uniquely determined. Let us call $\{x_i\}$ a Markushevich-Auerbach basis if the linear span of $\{x_i^*\}$ is weak* dense in X^* and $1=\|x_i\|_X=\|x_i^*\|_{X^*}$ for all i. Question: Is the problem about the existence of a Markushevich-Auerbach basis in an arbitrary infinite-dimensional separable Banach space still open? I am asking this question since I noticed that some recent papers (see Theorem 3.3 in http://arxiv.org/pdf/1604.03547.pdf) claim a solution of this problem, but I do not understand the argument.

Looking for an appropriate reference(s) for two conjectures on odd perfect numbers

(I apologize in advance if this question is unsuitable for MO. If so, please let me know and I will migrate it to MSE.) Let $\sigma(M)$ be the sum of the divisors of the positive integer M. For example, $\sigma(6)=1+2+3+6=12$. A number N is called perfect if $\sigma(N)=2N$. Euler proved that an odd perfect number N must have the form $N=q^k n^2$ where q is prime with $q \equiv k \equiv 1 \pmod 4$. We call q the Euler prime of N. Here are my questions: (1) Who is credited with making the conjecture that q is the largest prime factor of N? (2) Additionally, to whom should I attribute the conjecture that $k=1$? Should it be Descartes, Frenicle, or Sorli? (Added September 28 2016 For (2): In an edit to this MO post, it is stated that (per Beasley), "Dris $\ldots$ refers to Descartes' and Frenicle's claim (that $k=1$) as Sorli's conjecture; Dickson has documented Descartes's conjecture as occurring in a letter to Marin Mersenne in 1638, with Frenicle's subsequent observation occurring in 1657". As commented by Gerry, one would need to double-check Dickson's History of Number Theory to verify Beasley's statements.)

Remaining models conjectured to converge to SLE(6) or CLE(6)

I am wondering which models are conjectured (eg. numerically) to converge to SLE(6) (Schramm-Loewner evolution with $\kappa=6$) or CLE(6) (conformal loop ensemble). I am searching for a research topic in this very interesting area. The following are from Smirnov's 2007 review and elsewhere: 1) Critical percolation for lattices other than triangular eg. the square lattice. Any detailed review on this? 2) Fortuin-Kasteleyn random cluster model for $n=1$ and $x>x_{c}$, where x_{c} the critical edge weight. 3) For $O(1)$ but for $x\neq 1$ and $p\neq 1/2$, which correspond to the critical percolation case. 4) In the article "conformal invariance of hydrodynamic turbulence", they showed numerically that

zero-vorticity isolines correspond to SLE(6). 5) Random-field Ising model by Stevenson (2011).

What arguments do exist against defining completeness in NP using injective Karp reductions?

It is crucial to use the right notion of reduction to define completeness inside NP. Different notions of completeness inside NP may have significant impact on the properties of complete languages. Initially, P vs NP problem was formulated by Cook using polynomial-time Turing reductions. Later Karp refined the notion of completeness using polynomial-time many-one reductions. It is not known whether complete problems are equivalent under different notions of completeness (Cook vs Karp reductions). This post on CS Theory shows that defining completeness using injective Karp reductions would prove $P \ne NP$. The reason is that SAT is dense language and can not be reduced to a sparse language using injective Karp reductions. Mahaney's Theorem states that $P=NP$ if and only if there is a Karp reduction from SAT to a sparse language. Also, one of the answers highlights the fact that all known Karp reductions to NP-complete problems are injective. There is no known natural NP-complete problem via Karp reduction that can not be made one-to-one. If Cook had defined NP-completeness using injective Karp reductions then the P vs NP problem could not existed. What arguments do exist against defining completeness in NP using injective Karp reductions? Proving the existence (or non-existence) of polynomial-time algorithms for SAT would be more satisfactory way to resolve P vs NP but it is important to link it to the existence (or non-existence) of incomplete languages inside NP. Ladner's theorem states the $P\ne NP$ if and only if there exists an incomplete language in NP \ P (under Karp reductions).

Localizing Bondy's metaconjecture on hamiltonicity

Definitions: Let G be a graph on n vertices. G is Hamiltonian provided G has a cycle of length n. G is pancyclic provided G has a cycle of length ℓ for every $3 \leq \ell \leq n$. Background: Dirac [1952] showed that if G has $n \geq 3$ vertices and every vertex has degree at least $\frac{n}{2}$, then G is Hamiltonian. Bondy [1971] showed this condition implies that either G is the complete bipartite graph $K_{\frac{n}{2},\frac{n}{2}}$ or G is pancyclic. Bondy [1973] then proposed the following metaconjecture (which I quote from Kevash and Sudakov 2010): Metaconjecture. Almost any non-trivial condition on a graph which implies that the graph is Hamiltonian also implies that the graph is pancyclic. (There may be a simple family of exceptional graphs.) Another instance of this metaconjecture is the following corollary of a theorem of Clark [1981]. Let G be a connected, locally connected, claw-free graph on at least 3 vertices. Then G is pancyclic. Given property $\mathcal{P}$ (such as "connected"), a graph is locally $\mathcal{P}$ provided the neighborhood of every vertex is $\mathcal{P}$. A graph is claw-free provided it has no induced copies of $K_{1,3}$. Being claw-free is equivalent to being locally $\overline{K_3}$-free. It seems to me that such local properties might eliminate bothersome exceptional cases. Might we be able to prove a localized version of Bondy's metaconjecture such as the following? Tentative Subconjecture. Let $\mathcal{P}$ be a graph property such that every connected graph on at least 3 vertices that is locally $\mathcal{P}$ is Hamiltonian. Then every connected graph on at least 3 vertices that is locally $\mathcal{P}$ is pancyclic. A monotonicity assumption on the property--for example, if A satisfies $\mathcal{P}$ and A is a subgraph of B and $|A|=|B|$ then B satisfies $\mathcal{P}$--might also be useful. (This question is inspired by Ortrud Oellermann's presentation at the 2016 Prairie Discrete Math Workshop.)

Is the Gromov conjecture still open?

Today I read about Gromov's definition of minimal volume for smooth manifolds. $$\min {\rm Vol}(M):=\inf_{|K_g|\leq1}\{{\rm Vol}(M,g)\}.$$ Gromov's conjecture states that for every closed simply connected odd-dimensional manifold $\min {\rm Vol}(M)=0$. Is the Gromov conjecture still open? Can anybody give an example for this conjecture? Update: My teacher told to me that this conjecture can be solved by the Ricci flow method but I don't know how to use it. Can anybody give me an explanation to this? and how it works? Thanks.

Expectation of changing the gift choice

Suppose we are given two boxes, with one of gift valued n dollars and the other one valued twice as much. We can pick a box, and after open it we have the choice of switching to another box. Shall we switch? I was asked about this during some graduate student seminar. My reasoning is since two choices are equally likely, it is equally likely I will get a box half of the original value and a box twice the original value. So I should switch as the net expectation is positive. However, this implies that my original choice is somehow inferior to the choice after switch, which violates symmetry principle. Can someone help?

Square powers of hemicontinuous operators

Let H be an infinite dimensional real Hilbert space. A [not necessarily linear] mapping of H into itself is said to be hemicontinuous if it is continuous from each line segment of H to the weak topology of H (F.E. Browder / G.J. Minty). [Obviously, any linear operator is hemicontinuous.] Intuitively speaking, this is an extremely weak continuity requirement, still very useful, e.g., in the study of nonlinear elliptic boundary value problems. Now, here is my problem. Let U be an arbitrary (i.e., possibly discontinuous) selfmap of H. Is it true that there exists some hemicontinuous selfmap of H, say V, such that U 2 = V 2 ?

Any counter example for this: ${\phi(2^n-1)} \bmod \tau(2^n-1)=0$ for every integer $n \geq 1$?

I asked this question here In S.E but i don't received any resposnes for it, I would like to know if it is appropriate for M.O. I'm always interesting for properties of the following series : $ \sum_{n=1}^{\infty }\frac{\tau(2^n-1)}{\phi(2^n-1)}$ such that: $\tau(N)$ is the number of divisors of N and ϕ is Euler totient function, In this question i w'd be interest to know a little bit about the reciprocal of each term of the titled series at $N=2^n-1$ for every $n\geq 1$. Note:01 According to my calculations that i run in wolfram alpha from $n=1$ to 100 I have got this result as shown here such that it works which letting me to ask the following question. My question here is: Is ${\tau(2^n-1)}$ always divides $\phi(2^n-1)$ for every integer $n\geq 1$ and any counterexample for it? Thank you for any help !!!

V3-018113 | MO-255384

A conjecture about algebraic values of $(-q;\,-q)_\infty/(q;\,q)_\infty$

Recall that $(a;\,q)_\infty$ is the q-Pochhammer symbol: $$(a;\,q)_\infty=\prod_{n=0}^\infty(1-a \, q^n).\tag1$$ Its important special case $(q;\,q)_\infty=\prod_{n=1}^\infty(1-q^n)$ is sometimes called the Euler function. It appears in Euler's pentagonal number theorem, and its reciprocal $(q;\,q)_\infty^{-1}$ is the generating function for the partition numbers. It is also related to Jacobi theta functions and Ramanujan theta functions. Let $$f(x) = \frac{(-q;\,-q)_\infty}{(q;\,q)_\infty},\quad\text{where}\,\,q=e^{-\pi\sqrt x}.\tag2$$ In the OEIS entry A080054 there is an empirical observation by Simon Plouffe that apparently $f(1)=\sqrt[8]2$. Empirical (Simon Plouffe, Feb. 20, 2011): $$\sum_{n=0}^{\infty}e^{-\pi n}a(n) =\sqrt[8]2.$$ I did some numerical experiments related to this observation, and the outcomes suggest a fascinating stronger conjecture: Conjecture: For every $p\in\mathbb Q,\,p>0$, the value $f(p)$ is an algebraic number. For example, it appears that $$f(3/5) = \sqrt[8]{2} \cdot \sqrt[4]{9 \sqrt{5}+5 \sqrt{15}-11 \sqrt{3}-19},$$ and $f(13/7)$ is an algebraic number of degree 96 whose minimal polynomial is $$x^{96}-647442063456 \, x^{88}+16702438371168 \, x^{80}-529345497357824 \, x^{72}+4159684203040512 \, x^{64}-12099397290541056 \, x^{56}+16408771708010496 \, x^{48}-10607690933600256 \, x^{40}+2651923007078400 \, x^{32}-367001600 \, x^{24}+257949696 \, x^{16}-100663296 \, x^8+16777216$$ and an isolating rational interval is $(37/36,\,6/5)$. Is this conjecture new? Is it known to be true? If not, can you suggest any ideas how to (dis-)prove it?

Decidable open problems

Are there any significant open problems in mathematics which are clearly decidable (in that it is easy to write a clearly corresponding program which will eventually output either Yes or No (or whatever sort of answer, out of finitely many possibilities, is appropriate), though it may take an implausibly long time to do so) but which remain open? Dropping the qualifier "significant", examples of this sort of thing would be determining whether chess between perfect players results in a white win, black win, or stalemate; determining the $10^{10^{100}}$th decimal digit of π; etc. But none of these are of particular significance in mathematics, such that anyone would ordinarily list them as an open problem of note. So, though it is inherently a subjective judgment: Are there any good examples of significant open problems of this sort? (Edit: I nominate this question for reopening as NOT a duplicate, in that the question it has been marked a duplicate of specifically excludes problems that "naturally resolve after a finite computation", being interested only in problems which nontrivially reduce to finite computation. My interest is in either, but for me, the ideal examples are those that are manifestly finite computations from the start!)

there exist infinite many $n\in\mathbb{N}$ such that $S_n-[S_n]<\frac{1}{n^2}$

Let $S_n:=1+\frac12+\frac13+\ldots+\frac1n$. Is it true that the set of $n\in\mathbb N$ such that $$S_n-[S_n]<\dfrac{1}{n^2}$$ is infinite? Here, $[x]$ represents the largest integer not exceeding x. This question has been asked previously on math.SE without receiving any answers.

Proving $k = 1 \implies q = 5$, if $q^k n^2$ is an odd perfect number with Euler prime q

Let $N = q^k n^2$ be an odd perfect number with Euler prime q. We want to show that the biconditional $k = 1 \iff q = 5$ holds. It suffices to prove one direction, as the implication $q = 5 \implies k = 1$ was proved by Iannucci (Lemma 12, page 873). Per a comment from Pace: "Jose, you are misinterpreting the result from Iannucci. His number N is restricted to be an odd perfect number which additionally has all but at most two of its prime divisors less than 100. He goes on to prove that there are no such numbers, but along the way, in the lemma you cite, he shows that such numbers have restricted form." To this end, we show first that $$k = 1 \implies I(n^2) \leq 2 - \frac{5}{3q}.$$ The proof is easy. We refer the reader to this preprint. Next, we observe that $$I(n^2) = 2 - \frac{5}{3q}$$ implies that $$k = 1 \land q = 5,$$ (The assertion that follows only holds when $k=1$.) while $$I(n^2) < 2 - \frac{5}{3q}$$ implies $q > 5$. In particular, we have $$I(n^2) \leq 2 - \frac{5}{3q} \implies \bigg(\left(k=1\right) \lor \left(q>5\right)\bigg).$$ But we know that $$\bigg(\left(k=1\right) \lor \left(q>5\right)\bigg) \iff \bigg(q = 5 \implies k = 1\bigg).$$ Consequently, we have the chain of implications $$q = 5 \implies k = 1 \implies q = 5 \implies k = 1,$$ and we are done. Now here is my question: Is this "proof" logically sound? Update (December 30 2016) As in the given answer, we could only have the implication $$k = 1 \implies \bigg(q = 5 \implies k = 1\bigg),$$ which I agree is not the same as $$k = 1 \implies q = 5 \implies k = 1.$$

An explicit series representation for the analytic tetration with complex height

Tetration is the next hyperoperation after more familiar addition, multiplication and exponentiation. It can be seen as a repeated exponentiation, similar to how exponentiation can be seen as a repeated multiplication, and multiplication - as a repeated addition. Tetration is denoted $^n a$, where a is called the base and n is called the height, and is defined for $n\in\mathbb N\cup\{-1,\,0\}$ by the recurrence $$ {^{-1} a} = 0, \quad {^{n+1} a} = a^{\left({^n a}\right)},\tag1$$ so that $${^0 a}=1, \quad {^1 a} = a, \quad {^2 a} = a^a, \quad {^3 a} = a^{a^a}, \, \dots \quad {^n a} = \underbrace{a^{a^{{.^{.^{.^a}}}}}}_{n\,\text{levels}},\tag2$$ where power towers are evaluated from top to bottom. To simplify matters, we restrict our attention to real bases in the interval $1<a<e^{1/e}$. Under this restriction, the sequence $\{^n a\}$ is strictly increasing and converges to a limit: $$^\infty a=\lim_{n\to\infty} {^n a} = \frac{W(-\ln a)}{-\ln a},\tag3$$ where $W(z)$ denotes the principal branch of the Lambert W-function. To simplify our following exposition it is convenient to introduce a new variable q linked to a: $$q = \ln({^\infty a}) = {^\infty a} \cdot \ln a = -W(-\ln a).\tag4$$ The bounds on a imply $0<q<1$. The value q is closely related to the asymptotic growth of the tetration. In particular, it appears in remarkable limits: $$ \lim_{n\to\infty} \, \frac{{^{n+k} a}-{^n a}}{{^{n-k} a}-{^n a}} = -q^k, \quad \lim_{n\to\infty} \, \frac{{^{n+k} a}-{^\infty a}}{{^n a}-{^\infty a}} = q^k .\tag5$$ Definitions of addition, multiplication and exponentiation for fractional, negative and complex arguments are well-established. A natural extension of the tetration to fractional and complex heights is a long-standing question. It appears to be much less straightforward problem, mainly because exponentiation, unlike addition and multiplication, lacks both commutativity and associativity, and so tetration does not obey simple laws similar to $a^m \cdot a^n = a^{m+n}$ or $(a^m)^n = a^{m\,n}$. Despite these obstacles, several proposals aiming to extend the definition of the tetration to fractional and complex heights have been put forth. Their common goal is to define a function that agrees with the discrete tetration for all positive integer heights, and satisfies the functional equation $${^{z+1} a = a^{\left({^z a}\right)}\tag6$$ for all z in its domain. These conditions alone are not sufficient to determine a unique function, so additional natural restrictions (such as continuity, smoothness or analyticity) have been proposed, aiming to narrow down the set of candidate functions to a single and, in some sense, "the most natural" extension. The Wikipedia article on tetration is very cautious and indicates that, apparently, so far there is no consensus about which extension is "the one". Some of the proposals seem to lead to the same function, although apparently no rigorous proof of their equivalence has been published yet. The Citizendum article is written in a much bolder style, and refers to tetration as a unique well-defined function. But, overall, the study of tetration seems to be a quite isolated area of mathematics, with few connections to other topics. A few months ago I made some interesting conjectures related to tetration that I hoped I would prove soon. It appears that there are some connections between tetration and the theory of q-analogs. Unfortunately, I have not made much progress in proving them since then (although I have learnt a lot about q-series), so I finally decided to post them here and ask for your help. First, let's recall some definitions. The q-Pochhammer symbol: $$(p;\,q)_\infty = \prod_{k=0}^\infty(1-p\,q^k)\tag7$$ $$(p;\,q)_z = \frac{(p;\,q)_\infty}{(p\,q^z;\,q)_\infty},

\quad z\in\mathbb C\tag8$$ It easily follows that $$(p;\,q)_n = \prod_{k=0}^{n-1}(1-p\,q^k), \quad n\in\mathbb N\tag9$$ The q-binomial coefficients (also known as the Gaussian binomial coefficients): $${r \brack s}_q = \frac{(q;\,q)_r}{(q;\,q)_s \, (q;\,q)_{r-s}}.\tag{10}$$ From now on we assume that a and, consequently, q are fixed. Let us define an analytic function $t(z)$ by the following series: $$ t(z) = \sum_{n=0}^\infty \sum_{k=0}^n (-1)^{n-k} \, q^{\binom {n-k} 2} {z \brack n}_q {n \brack k}_q ({^k a}).\tag{11} $$ This formula can be seen as a combination of the direct and reverse q-binomial transforms. It can be proved by induction that for $n\in\mathbb N, \, t(n)={^n a}$, so $t(n)$ satisfies the functional equation for tetration (6) at least for positive integer arguments. Indeed, partial sums of (11) can be seen as Lagrange interpolating polynomials in powers of q^z that exactly reproduce tetration values for progressively larger initial segments of $\mathbb N$. Numeric evidence suggests that adding new points to the interpolating polynomial of this form does not result in erratic oscillations of its arcs between existing points (i.e. Runge's phenomenon does not occur), but rather makes them converge to a monotone function satisfying the functional equation for the tetration (6). So we have: Conjecture 1. The series $t(z)$ converges at least in the half-plane $\Re(z)>-2$ to an analytic function that satisfies the functional equation for tetration $t(z+1)=a^{t(z)}$ for all arguments in its domain of analyticity. Conjecture 2. The function $t(z)$ is periodic with a purely imaginary period $\tau = 2\pi n i/\ln q$, and admits an analytic continuation to the half-plane $\Re(z) \le -2$ by repeated backward application of the functional equation (6). There it has a countable set of isolated singularities at $z = m + \tau\,n, \,m,n\in\mathbb Z, \, m \le -2$, and a countable set of branch cuts that can be made along horizontal rays at $z = x + \tau\,n, \, n\in\mathbb Z, \, x\in\mathbb R, \, x < -2$. Conjecture 3. For real $x>-2$, the derivative $t'(x)$ is a completely monotone function. Conjecture 4. There is only one analytic function that vanishes at $z=-1$ and satisfies both the functional equation for the tetration (6), and the complete monotonicity condition from the Conjecture 3. Related questions: [1][2][3].

Reconstructing analytic tetration with a complex height from a thinner set of points

This is a follow-up to my previous question An explicit series representation for the analytic tetration with complex height. Recall the definition (11) from there: $$t(z) = \sum_{n=0}^\infty \sum_{k=0}^n (-1)^{n-k} \, q^{\binom {n-k} 2} {z \brack n}_q {n \brack k}_q ({^k a}).\tag1$$ Let us introduce additional parameters $p,s\in\mathbb Z^+$ into this formula (changes are shown in red): $$t(\color{red}p,\color{red}s,z) = \sum_{n=0}^\infty \sum_{k=0}^n (-1)^{n-k} \, q^{\,\color{red}p \, \binom {n-k} 2} {(z-\color{red}s)/\color{red}p \brack n}_{q^{\color{red}p}} {n \brack k}_{q^{\color{red}p}} ({^{\color{red}p\,k+\color{red}s} a}).\tag2$$ Basically, it means that we build our function from a thinner and shifted sample of tetration values. Conjecture 1. Values of integer parameters p,s do not matter, i.e. $$\forall p,s\in\mathbb Z^+, \, t(p,s,z) = t(z).$$ Let us generalize the definition of $t(p,s,z)$ to real-valued parameters $p,s\in\mathbb R^+$ (note that we switch to continuous tetration $t(z)$ in the last factor): $$t_{\mathbb R}(p,s,z) = \sum_{n=0}^\infty \sum_{k=0}^n (-1)^{n-k} \, q^{\,p \, \binom {n-k} 2} {(z-s)/p \brack n}_{q^p} {n \brack k}_{q^p} \color{red}t(p\,k+s).\tag3$$ Conjecture 2. Values of real parameters p,s do not matter, i.e. $$\forall p,s\in\mathbb R^+, \, t_{\mathbb R}(p,s,z) = t(z).$$ Can we prove these conjectures? If yes, it means that we do not need all values of the discrete tetration (represented by the factor $(^k a)$ in (1)) to build a formula for the analytic tetration, but a very thin (although still infinite) subset of them already contains enough information to exactly reconstruct its values at all points in between (including skipped integer points). Can we make a step further and find a way to construct an explicit series for the analytic tetration that relies only on a finite set of values of the discrete tetration?

A seemingly simple inequality

Let $a_i,b_i\in\mathbb{R}$ and $n>1$, does the inequality $$ \left(\sum_{i=1}^n a_i^2\right)\left(\sum_{i=1}^n b_i^2\right)+\left(\sum_{i=1}^na_i b_i\right)^2\ge \sqrt{\left(\sum_{i=1}^n a_i^4\right)\left(\sum_{i=1}^n b_i^4\right)}+\sum_{i=1}^na_i^2b_i^2 $$ hold true? Observe that a_i and b_i are not required to be non-negative. I ran an extensive number of numerical simulations and no counterexample showed up yet. Note 1. The inequality holds true for $n=2$, as showed here. Note 2. This conjecture was formulated by Fedor Petrov in an attempt to provide a solution to a particular case of this question. Note 3. I have posted this question on math.SE some time ago but it has received no answer, so I cross-posted it here. Note 4. As Fedor Petrov rightly observed in his answer below, the inequality also follows by an argument used in one of his answers in the above-cited question. However, I decided to accept Markus Sprecher's answer because of its conciseness and clarity.

A curious series related to the asymptotic behavior of the tetration

The tetration is denoted $^n a$, where a is called the base and n is called the height, and is defined for $n\in\mathbb N\cup\{-1,\,0\}$ by the recurrence $$ {^{-1} a} = 0, \quad {^{n+1} a} = a^{\left({^n a}\right)},\tag1$$ so that $${^0 a}=1, \quad {^1 a} = a, \quad {^2 a} = a^a, \quad {^3 a} = a^{a^a}, \, \dots \quad {^n a} = \underbrace{a^{a^{{.^{.^{.a}}}}}}_{n\,\text{levels}},\tag2$$ where power towers are evaluated from top to bottom. Let a be a real number in the interval $1<a<e^{1/e}$. It is convenient to introduce a notation $$\lambda = -W(-\ln a),\tag3$$ where $W(z)$ denotes the principal branch of the Lambert W-function, satisfying $W(z) \, e^{W(z)}=z$. Note that the restrictions on a imply $0<\lambda<1$. We may also observe that $\ln\ln a = - \lambda + \ln \lambda$. The sequence $\{^n a\}$ converges to a limit $$\lim_{n\to\infty} {^n a} = e^\lambda = \frac\lambda{\ln a}.\tag4$$ Its asymptotic behavior can be represented as $${^n a} = e^\lambda - c_{\lambda} \cdot \lambda^n + O(\lambda^{2n}),\tag5$$ where c_{λ} is some positive coefficient depending on λ (or, equivalently, on

a). It is known that the coefficients in $O(\lambda^{2n})$ and all higher-order terms can be expressed in a closed form via c_{λ}. But, apparently, the dependency between λ and c_{λ} has no known simple representation. Here is how its graph looks: It appears to have a maximum near (or exactly at?) $\lambda = \ln 2$ that corresponds to $a=\sqrt2$. Numerical evidence suggests that c_λ has a Taylor-Maclaurin series expansion with rational coefficients $$c_\lambda = \frac{\lambda }{1!}+\frac{\lambda ^2}{2!}-\frac{2 \lambda ^3}{3!}-\frac{11 \lambda ^4}{4!}-\frac{44 \lambda ^5}{5!}-\frac{89 \lambda ^6}{6!}-\frac{636 \lambda ^7}{7!}-\frac{615 \lambda ^8}{8!}-...\tag6$$ (more numerators can be found here) I could not find a formula for the coefficients (apparently, they are not yet in the OEIS), and I do not even have a proof that the coefficients given above are exact, so I am asking for your help with it. Is it possible to sum this series in terms of known special functions? Is it actually unimodal as is suggested by its graph? What is the exact location of its maximum? Related questions: [1][2][3][4][5][6].

Can there be a polymath project for mathematical physics?

My hunch is that it might be possible to create something like https://polymathprojects.org/ for mathematical physics and I'd like to know whether MathOverflow users can recommend some appropriate problems. As Abdelmalek Abdessalam pointed out in the comments below such a platform can potentially be used to develop research programs in mathematical physics that are suitable for polymath type collaborative work. The gist of this project would be to use collaborate problem-solving to tackle open problems in mathematical physics. Timothy Gowers wrote a seminal blog post on the subject here: Is massively collaborative mathematics possible? There's a good point made by a commenter below as to why not simply use the current polymath platform. Well, I think that it would be easier for such a platform to succeed and gain support among mathematical physicists if it was maintained by mathematical physicists and focused mainly on problems in the area of mathematical physics. This is not the current setup of the Polymath project.

What is the status on this conjecture on arithmetic progressions of primes?

The Green-Tao theorem states that for every n, there is an arithmetic sequence of length n consisting of primes. For primes, p, let $P(p)$ be the maximum length of an arithmetic progression of primes whose least element is p. Is it known whether $P(p)=p$ for every prime? (This clearly generalizes the Green-Tao theorem, asserting that long progressions show up "as soon as possible." Note that $P(p) \leq p$ by viewing the progression mod p.)

Several conjectured identities for polylogarithms

I asked a question at M.SE a couple of years ago about polylogarithms $\!^{[1]}$$\!^{[2]}$$\!^{[3]}$$\!^{[4]}$ where I conjectured $$720\,\operatorname{Li}_4\!\left(\tfrac12\right)-2160\,\operatorname{Li}_4\!\left(\tfrac13\right)+2160\,\operatorname{Li}_4\!\left(\tfrac23\right)+270\,\operatorname{Li}_4\!\left(\tfrac14\right)+540\,\operatorname{Li}_4\!\left(\tfrac34\right)+135\,\operatorname{Li}_4\!\left(\tfrac19\right)\\ =19\pi^4+30\left(\pi^2-\beta^2\right)\left(10\alpha^2-12\alpha\beta+3\beta^2\right)-30\,\alpha^2\left(19\alpha^2-24\alpha\beta+8\beta^2\right)\!,\\ \text{where $\alpha=\ln2,\,\beta=\ln3$.}$$ I put a bounty on it recently, but it still remains unanswered. So, I decided to re-post it here. Also, I recently discovered several similar conjectures for $\operatorname{Li}_5(z)$ involving powers of the golden ratio $\phi=\frac{1+\sqrt5}2$: $$4455\,\operatorname{Li}_5\left(\phi^{-2}\right)-1215\,\operatorname{Li}_5\left(\phi^{-4}\right)-360\,\operatorname{Li}_5\left(\phi^{-6}\right)+15\,\operatorname{Li}_5\left(\phi^{-12}\right)\\ =3015\,\zeta(5)-702\ln^5\phi+180\,\pi^2\ln^3\phi-38\,\pi^4\ln\phi$$ $$45000\,\operatorname{Li}_5\left(\phi^{-2}\right)-16875\,\operatorname{Li}_5\left(\phi^{-4}\right)-144\,\operatorname{Li}_5\left(\phi^{-10}\right)+9\,\operatorname{Li}_5\left(\phi^{-20}\right)\\ =28944\,\zeta(5)-6000\ln^5\phi+1600\,\pi^2\ln^3\phi-356\,\pi^4\ln\phi$$ $$15660\,\operatorname{Li}_5\left(\phi^{-2}\right)-19440\,\operatorname{Li}_5\left(\phi^{-4}\right)+7680\,\operatorname{Li}_5\left(\phi^{-6}\right)+2430\,\operatorname{Li}_5\left(\phi^{-8}\right)-15\,\operatorname{Li}_5\left(\phi^{-24}\right)=5025\,\zeta(5)+2088\ln^5\phi-240\,\pi^2\ln^3\phi-28\,\pi^4\ln\phi$$ How can we prove these conjectures? Are there other similar identities of this kind?

A conjecture about certain values of the Fabius function

The Fabius function is a smooth monotone function $F:[0,1]\to[0,1]$, satisfying functional equations $$F(0)=0, \quad F(1-x)=1-F(x)\tag1$$ and $$F'(x) = 2 \,F(2 x) \quad \text{for} \,\, 0<x<1/2.\tag2$$ The function F assumes rational values at dyadic rational arguments. In particular, it is known $\!^{[1]}$$\!^{[2]}$ that $$F\left(2^{-n}\right) = \frac1{n! \, 2^{\binom{n+1}2}} \, \sum_{m\ge0}\binom n {2m} \, c_m,\tag3$$ where c_m are defined by the recurrence $$c_0 = 1, \quad c_n = \frac1{(4^n - 1)(2n+1)} \, \sum_{m\ge1} \binom{2n+1}{2m+1} \, c_{n-m}.\tag4$$ Note that only finite number of terms in each sum are non-zero. The values $F\left(2^{-n}\right) $ appear as A272755 / A272757 in the OEIS. Let $$a_n = F\left(2^{-n}\right) \, 2^{\binom {n-1}2} \, (2n)! \, \prod_{m=1}^{\lfloor n/2\rfloor}\left(4^m - 1\right).\tag5$$ This sequence begins $$1, \, 5, \, 15, \, 1001, \, 5985, \, 2853675, \, 26261235, \, 72808620885, \, 915304354965 \, ...\tag6$$ (see more terms here) I conjecture that all terms of this sequence are integers. How can we prove (disprove) this conjecture?

Primes dividing functions defined by linear recurrence relations with constant coefficients

For Fibonacci numbers F_n it holds that $p|F_{p-(\frac{5}{p})}$, if p is an odd prime (Legendre symbol). I guessed that the number 5 came from the roots of the characteristic polynomial and tried the following approach: Given $a,b\in\mathbb Z^+$ (for simplicity), and let $F_{a,b}:\mathbb N\to\mathbb N$ be a function such that $F_{a,b}(0)=0$, $F_{a,b}(1)=1$ and $F_{a,b}(n+1)=a\cdot F_{a,b}(n)+b\cdot F_{a,b}(n-1)$. Conjecture: If a,b are co-prime and $p>2$ is a prime that doesn't divide b, then $F_{a,b}\left(p-\left(\frac{a^2+4b}{p}\right)\right)\equiv 0\pmod p$, Is this conjecture correct and known? I have tested the conjecture with 50000 randomly selected a,b,p. That is, three numbers $1\le a',b'\le 100$ and $3\le p'\le 10000$ are selected with uniform distribution, then $a=\frac{a'}{gcd(a',b')},b=\frac{b'}{gcd(a',b')}$ and p is set to the least prime $\ge p'$.

Dissecting trapezoids into triangles of equal area

[Lightly edited for copy and proper formatting of mathematics. -- Pete L. Clark] The Background: Let T be a trapezoid. Sherman Stein, using valuation theory, showed that if T is dissectible into n triangles of equal area, then $\frac{n}{(r+1)}$, where r is the ratio of the parallel sides, is an algebraic integer. See Monsky and Jepsen, Constructing equidissections for certain classes of trapezoids, Discrete Mathematics, 308 23 (2008) 5672-5681. In particular r is algebraic. If r is in $\mathbb{Q}$, a diagonal of T divides T into two triangles of commensurable area, so T has an "equidissection". Stein showed that if r is a root of a degree 2 element of $\mathbb{Q}[z]$ [i.e., the univariate polynomial ring over $\mathbb{Q}$ -- PLC] with both roots positive, then T is equidissectible. Using ideas of Stein and Jepsen I showed that if r is a root of a degree 3 or 4 element of $\mathbb{Q}[z]$ with all roots in the open right half-plane, then once more T is equidissectible. (It's not clear that my proof can be adapted to degree greater than 4). In contrast, whenever the algebraic r has a conjugate over $\mathbb{Q}$ that's not in the open right half-plane, nothing is known about the equidissectibilty of T. Stein conjectured that when r has a $\mathbb{Q}$-conjugate not in this half plane, then T is not equidissectible. I ask: The Question: Is it true that if r has a $\mathbb{Q}$-conjugate not in the open right half-plane then T cannot be dissected into triangles of equal area? (For no such r has an equidissection of T or a proof of non-equidissectibility been found).

Can we color Z^+ with n colors such that a, 2a, ..., na all have different colors for all a?

For example for n=2 coloring odd numbers red, numbers of the form 4k+2 blue and so on works. This problem was posed in the KoMaL for n+1 prime, by Peter Pach Pal. I verified it for all n<30, I think with a computerprogram one can easily verify it for much bigger numbers by trying certain periodic colorings. Ideas. As there is a lot of discussion going on, I thought I share here my attempts as Ewan and Gowers took similar paths. First of all, if we denote the primes by p_i and the largest prime not bigger than n by p_d, then it is sufficient to color the numbers of the form $\Pi p_i^{\alpha_i}$. This is equivalent to coloring $\mathbb Z^d$ with n colors such that the translates of a special poliomino are all rainbow colored, meaning they contain all n colors. This is also equivalent to tiling the space with translates of this poliomino. The easiest way to give a coloring is if we have some nice periodicity, eg. if n+1 is prime, then $\Pi p_i^{\alpha_i} \mod (n+1)$ is such, whenever we go in a direction, it corresponds to an authomorphism of Z_{n+1}^*. Another possibility is to give a "linear" coloring using the addition $\mod n$, for example for $n=5$, one can take $x+3y+4z \mod 5$. So far I could always find such a linear coloring but I cannot prove that it always exist, eg. we have too many constraints to use the combinatorial nullstellensatz.

Maximum matching in a graph with no "shortcuts"

For a directed acyclic graph (DAG) G, denote by $G^\star$ the undirected graph obtained from G by ignoring direction of its arcs. Let $e(G)=e(G^\star)$ be the number of arcs in G (or edges in $G^\star$). An arc (u,v) in G is called a shortcut if there exists a directed path from u to v in G different from (u,v). In our research, we came up with the following conjecture: Conjecture. Let G be a DAG without shortcuts such that the indegree and outdegree of every vertex is each ≤ 2. Then there exists a matching in $G^\star$ of size at least $\frac{1}{4}e(G)$. Small examples seem to support this conjecture, although a general proof appears quite elusive. The lower bound $\frac{1}{5}e(G)$ here is almost trivial (and holds even with shortcuts), and with some effort we were able to prove the bound $\frac{2}{9}e(G)$. Any help in proving or disproving the conjecture will be appreciated. P.S. Apparently it is crucial that $G^\star$ results from a DAG. E.g., a similar statement for a generic undirected graph of degree at most 4 and no cycles of length 3 (which follows from the absence of shortcuts G) does not hold.

Coiling Rope in a Box

What is the longest rope length L of radius r that can fit into a box? The rope is a smooth curve with a tubular neighborhood of radius r, such that the rope does not self-penetrate. For an open curve, each endpoint is surrounded by a ball of radius r. For a box of dimensions

$1{\times}1{\times}\frac{1}{2}$ and rope with $r=\frac{1}{4}$, perhaps $L=\frac{1}{2}+\frac{\pi}{4} \approx 1.3$, achieved by a 'U': I know packing circles in a square is a notoriously difficult problem, but perhaps it is easier to pack a rope in a cube, because the continuity of the curve constrains the options? (I struggle with this every fall, packing a gardening hose in a rectangular tub.) I am more interested in general strategies for how to best coil the rope, rather than specific values of L. It seems that if r is large w.r.t. the box dimensions (as in the above example), no "penny-packing" cross-sectional structure is possible, where one layer nestles in the crevices of the preceding layer. This is a natural question and surely has been explored, but I didn't find much. Edit 1. It seems a curvature constraint is needed to retain naturalness: The curve should not turn so sharply that the disks of radius r orthogonal to the curve that determine the tubular neighborhood interpenetrate. Edit 2 (26Jun10). See also the MO question concerning decidability. Edit 3 (12Aug10). Here is an observation on the 2D version, where a $1 {\times} 1 {\times} 2r$ box may only accommodate one layer of rope. If $k=\frac{1}{2r}$ is an even integer, then I can see two natural strategies for coiling the rope within the box: $\qquad \qquad \qquad \qquad \qquad$ Red is rope core curve, blue marks the rope boundary. Interestingly, if I have calculated correctly, the length of the red rope curve is identical for the two strategies: $$L = 2 (k-1)[r \pi/2] + 2(k-1)^2 r \;. $$ For $r=\frac{1}{16}$, $k=8$ as illustrated, $L=\frac{7\pi}{16} + \frac{49}{8} \approx 7.5$. (As a check, for $r=\frac{1}{4}$, $k=2$, and L evaluates to $\frac{\pi}{4}+\frac{1}{2}$ as in the first example above.)

Surface bundles over surfaces with(out) flat structure

I vaguely remember that I once attended a seminar or conference talk in which it was mentioned that the following question is open. Is there a (smooth) surface bundle over a surface $\Sigma_h \to E \to \Sigma_g$ that does not admit a flat structure? (Equivalently, one can ask whether there is a homomorphism $\pi_1(\Sigma_g) \to \pi_0 \text{Diff}(\Sigma_h)$ that cannot be lifted to the group of diffeomorphisms.) What is the status of this question, and could somebody point out a reference that mentions this as an open question? Finally, is something known for small values of g,h (but still $g,h \geq 2$)? (In case you do not understand what I am asking, I can very much recommend reading the last chapter of Morita's book Geometry of Characteristic Classes.)

Hausdorff's question on ω_1-gap

I read here that the following problem of Hausdorff is apparently still open. Is there a maximal branch C in the poset ω^ω with the eventual domination order, such that C has no ω_1-gap. My questions concerning the above problem are: What is its current status? What are the consequences of its solution? negative, independence or positive.

Generalization of Legendre`s conjecture

Legendre`s conjecture states that there is always a prime between n^2 and $(n+1)^2$ for every natural n. It is natural to create following generalization: Is it true that for every $\varepsilon \in (0,1]$ there exists natural number $n_0(\varepsilon)$ such that for every $n \geq n_0(\varepsilon)$ there is always a prime between $n^{1+\varepsilon}$ and $(n+1)^{1+\varepsilon}$? I do not know if some results from number theory do not allow this generalization to be true but if it is not known is it true or not what is known, if anything, about this generalization of Legendre`s conjecture?

Is the fundamental group of any compact hyperbolic 3-manifold embeddable into a p-adic group?

Is it true that for every compact hyperbolic 3-manifold M there exists a prime p, a finite field extension $K/\mathbb{Q}_p$, and an injective group homomorphism $$\tau \colon \pi_1(M) \to \mathrm{PSL}_2(\mathcal{O}_K) ?$$ Here $\mathcal{O}_K$ is the ring of integers of K. This question is obviously related to the existence of faithful low dimensional representation of hyperbolic groups (see the following survey by Aschenbrenner, Friedl, and Wilton). An affirmative solution will give a (partial) confirmation of Conjecture 1 from this paper by Luo. A paper by Calegari and Emerton also discusses such group homomorphisms τ. Note that the answer is obviously 'yes' if M is arithmetic.

Is Thompson's Group F amenable?

Last year a paper on the arXiv (Akhmedov) claimed that Thompson's group F is not amenable, while another paper, published in the journal "Infinite dimensional analysis, quantum probability, and related topics" (vol. 12, p173-191) by Shavgulidze claimed the exact opposite, that F is amenable. Although the question of which, if either, was a valid proof seemed to be being asked by people, I cannot seem to find a conclusion anywhere and the discussion of late seems to have died down considerably. From what I can gather, Shavgulidze's paper seems unfixable, while the validity of Akhmedov's paper is undecided (although it may of course be decided now). So, does anyone know if either of these papers is valid?

Is there a composite number for which this game with composite numbers never ends?

I created some "game" a couple of days ago and modified it during the last hour or so and now I want to present it to you. Choose some natural number >1. If the chosen natural number is of the form p^n, where $p \in \mathbb P$ and $n \in \mathbb N$ then the game is over. But if the chosen number has $k \geq2$ different prime factors (abbreviated as dpf in the rest of the text) then we add to that number the next number which also has k dpf. If after adding we arrive at the number of the form p^n then the game is over. But if after adding we arrive at a number that has $l \geq 2$ dpf then we add to it the next number which has l dpf. We continue in this way until we arrive at the number of the form p^n and then the game is over. To clarify if something is not clear, let us take as an example the number 12. It has two dpf and the next number that has two dpf is 14 so we arrive at $12+14=26$ which has two dpf, the next number that has two dpf is 28 so we arrive at $26+28=54$ which has two dpf and the next one with two dpf is 55 so we arrive at $54+55=109$ which is prime and the game is over. Does there exist at least one composite number for which this game is never over? This seems (at least to me) as a very hard question and I would like to call the composite numbers for which the game never ends an awesome numbers, although maybe the number of those numbers equals zero, but that is yet to be proved.

Which motivic cohomology groups of complex numbers are non-torsion?

I would like to know which motivic cohomology groups of complex numbers are non-zero and ("better") non-torsion, i.e., for which (i,j) the ith cohomology of the complex ${\mathbb{Q}}(j)$ over $\mathbb{C}$ is not zero. I would like to know both which of these groups are known to be non-zero (and also known to be "large") unconditionally and also which of them shouldn't vanish according to some conjectures. Certainly, my question can be easily translated into the language of K-theory.

Open bilinear maps that are not uniformly open

A map $f\colon X\to Y$ between metric spaces is uniformly open whenever for each $\varepsilon >0$ there is $\delta >0$ such that for any $x\in X$ one has $$B_Y\big(f(x),\delta\big)\subseteq f\big(B_X(x,\varepsilon)\big), $$ where B_X, B_Y denote open balls in the respective spaces. Uniformly open maps have the property that they are surjective as long as the codomain is connected. The exponential function is an example of an open map that is not uniformly open. A continuous, surjective bilnear map $A\colon X\times X\to Y$ between Banach spaces need not be open, contrary to the linear case. (Already matrix multiplication is an example; another example is multiplication in $C[0,1]$ in the case of real scalars; this is due to Fremlin). Is there an example of a continuous, bilinear and surjective map between Banach spaces that is open but not uniformly open? I have a suspicion that it could be already convolution in $\ell_1(\mathbb Z)$ but I am not sure how to approach this (in the latter case I know that it is not uniformly open as $\ell_1(\mathbb{Z}/n\mathbb{Z})$ do not have equi-uniformly open convolutions). Edit (27.06.2017). This question was also asked in a paper by Balcerzak, Behrends, and Strobin (Banach J. Math. Anal. 10 (2016), no. 3, 482-494). I would also welcome examples of n-linear maps with this property, where n is arbitrary.

Random N-body problem

Suppose there are N unit-mass particles whose initial positions are uniformly distributed in a unit-radius disk. Each particle is assigned a randomly oriented initial velocity vector v_i of length 1 (green below). Added: Robert Israel's incisive comment suggests that I should also stipulate that $\sum_i v_i = 0$. Then the particles act upon one another via inverse-square gravity. Dots show initial positions inside unit disk. Green vectors: initial velocity; red vectors: final velocity. Q. What is the probability that $k \ge 1$ of the N particles remain within a disk of some radius $R \ge 1$ forever? In the illustration above, $N=8$ and $R=3$. (But I do not trust my crude simulations.) I am wondering if the answer is: zero, independent of k and R and the gravitational constant? Perhaps the answer differs for points in $\mathbb{R}^2$ vs. points in $\mathbb{R}^3$ (or $\mathbb{R}^d$, $d > 3$)?

Does there exist a comprehensive compilation of Erdos's open problems?

Fan Chung and Ron Graham's book Erdos on Graphs: His Legacy of Unsolved Problems (A. K. Peters, 1998) collects together all of Erdos's open problems in graph theory that they could find into a single volume, complete with bounties where applicable. Of course Erdos posed many other open problems in combinatorics and number theory that do not appear in this book. I once heard a rumor that some people were working on a project to publish a similar but more comprehensive book or series of books, covering all of Erdos's open problems, but I don't know if the rumor is true. Does such a compilation exist? If not, is there anything else like this besides Chung and Graham's book?

Limit cycles as closed geodesics(2)

Hilbert 16th problem asks for a uniform upper bound $H(n)$ for the number of limit cycles of a polynomial vector field of degree n on the plane. Here is an updated proof of the finitness part of the Hilbert 16th problem: http://www.mathnet.ru/php/archive.phtml?wshow=paper&jrnid=im&paperid=8352&option_lang=eng This problem is open even for $n=2$. In this question, by a quadratic vector field we mean a polynomial vector field $$P(x,y)\partial_x+Q(x,y) \partial_y\;\;\;(V)$$ where $P,Q\in \mathbb{R}[x,y]$ are polynomials of degree 2 with $P(0,0)=Q(0,0)=0$. So the question is that (Hilbert 16th problem for n=2) Is $H(2)$ a finite number? As a possible approach to this question we would like to look at limit cycles of a vector field as closed geodesics. Namely we would like to put a Riemannian metric on the (regular part of the) phase space such that the trajectories of the vector field would be unparametrized geodesics. By regular part we mean the complement of singularities of the vector field. Thus each limit cycle would be a closed geodesic. Then using Gauss Bonnete theorem we try to count the number of closed geodesics. So the sign of the Gaussian curvature play a very important role. But the first problem is that, regardless of the curvature sign, is there a Riemannian metric on the regular part of the phase space such that the trajectories of the vector field would be geodesic. This example shows that, for a polynomial vector field of arbitrary degree such metric does not necessarily existed. But for quadratic vector field the situation is different as follows. In the following C is the algebraic curve $$yP(x,y)-xQ(x,y)=0\;\;\;\;\;(C)$$ Observation: There is a Riemannian metric on $\mathbb{R}^2 \setminus C$ such that all solutions of Quadratic vector field (V) are geodesics. Furthermore every limit cycle of $(V) $ which surround the origin can not intersect the curve C The proof of this observation is based on Proposition 6.7 and 6.8 as follows: Geometry of foliation So we are sure that, on the complement of the above algebraic curve C, we have a Riemanian metric such that all solutions of (V) are geodesics. The methods of the proof of the Propositions 6.7 and 6.8 in the book Geometry of foliation suggest that we choose a Riemannian metric whose orthonormal base is the following: $$\left\{\frac{x^2+y^2}{yP(x,y)-xQ(x,y)}V,\ \frac{1}{x^2+y^2}W\right\}.$$ where $V=P\partial_x +Q\partial_y$ is the quadratic vector field as in (V) and W is the radial vector field $W=x\partial_x+y\partial_y$. In fact W, as it is required in the proof of the above two propositions, lies in the kernel of $1_$ form $\psi=\frac{1}{x^2+y^2}(ydx-xdy)$. This $1_$ form is very essential to apply propositions 6.7 and 6.8 in the above reference. In fact this is a closed form which is identically equal to 1 on the first vector of the above orthonormal frame.That is $\psi(\frac{x^2+y^2}{yP-xQ}(V))=1$. I am really indebted to Ben McKay who suggested the $1_$form $d\theta$ as a required $1_$ form for possible satisfactions of proposition 6.8. On the other hand the method of the proof of the Proposition 6.7 shows that, on the complement of C, all trajectories of V are geodesics for the metric arising from the above orthonormal frame. Moreover we are free to rescale the second vector of the frame, arbitrarily. Now the main problem is that we control the sign of the curvature of such metric to make facilities to count the number of closed geodesics. In fact we use the Gauss Bonnete theorem. Call the curvature of this metric κ. Question: When a quadratic vector field V does not have a center on the plane, is the curve $$\{(x,y)\mid \kappa(x,y)=0\}$$ transverse to V? If not, what appropriate rescaling of the the second vector $ \frac{1}{x^2+y^2} W$ of the orthonormal frame would give a positive answer? Notes: 1)A center is a singularity which is surrounded by a band of closed orbits. For quadratic vector fields they are classified at this paper. 2)Of course existence of a positive answer to this question implies that $H(2)$ is finite. Because the number of limit cycles of V which suround the origin can be uniformly bounded since $\kappa=0$ is an algebraic curve so in every connected component of this algebraic curve, we have at most on limit cycle surrounding origin. On the other hand there are at most 2 nest of limit cycles. So this would imply that $H(2)<\infty$ The motivation for this post is mentioned in this answer and this post. However the initial motivation is mentioned in page 3, item 5 of this arxiv note.

A cubic system with two nested limit cycles with opposite orientations(2)

The second part of Hilbert's 16th problem not only concerns "The number of limit cycles of a polynomial vector field", but also the position and configuration of of those limit cycles with respect to each other. However the primary and the usual interpretation of the concept "Relative Position" is that "Whether two given limit cycles are nested closed curves or not" but the following post is a motivation to consider other types of questions about configuration of limit cycles, for example "Can two nested limit cycles have opposite orientation?" A cubic system with two nested limit cycles with opposite orientations In this regard we focus on cubic polynomial system and ask the following question: What is an example of Cubic polynomial vector field $$\begin{cases} x'=P(x,y)\\ y'=Q(x,y) \end{cases}$$ such that two nested closed orbits C_1, C_2 of the system surrounds an annular region R such that R does not contain any singular point and the flow orientation of C_1 is opposite to the flow-orientation of C_2? There is a very interesting example of degree 5 here but we search for degree 3

Polynomials having a common root with their derivatives

Here is a question someone asked me a couple of years ago. I remember having spent a day or two thinking about it but did not manage to solve it. This may be an open problem, in which case I'd be interested to know the status of it. Let f be a one variable complex polynomial. Supposing f has a common root with every $f^{(i)},i=1,\ldots,\deg f-1$, does it follow that f is a power of a degree 1 polynomial? upd: as pointed out by Pedro, this is indeed a conjecture (which makes me feel less badly about not being able to do it). But still the question about its status remains.

Periodic Automorphism Towers

In Scott's classic textbook on Group Theory, he asks: Suppose that G is a finite group. Is the sequence of isomorphism types of the groups $Aut^{(n)}(G)$ for $n \in \mathbb{N}$ eventually periodic? Here $Aut^{(2)}(G) = Aut(Aut(G))$ etc. Equivalently, is the sequence $|Aut^{(n)}(G)|$ always bounded above? It apparently remains opens whether the sequence of automorphism types of $Aut^{(n)}(G)$ is in fact always eventually constant. (A wonderful theorem of Wielandt says that if G is a finite centerless group, then the sequence is eventually constant.) So I would like to ask: Does there exists a finite group such that $Aut(G) \not\cong G$ but $Aut^{(n)}(G) \cong G$ for some $n \geq 2$? Edit: Joel has pointed out that my question is perhaps even open for infinite groups. This sounds like an interesting question which doesn't seem amenable to the standard tricks.

Splitting of ordinals of oscillation ranks of a Baire 1 function

Denny and Tang proved that Theorem 2.3 Let (f_n) be a sequence in $\mathfrak{B}_1(K)$ converging pointwise to a function $f.$ Suppose $\sup\{ \beta(f_n):n\in\mathbb{N} \} \leq \beta_0$ and $\gamma((f_n)) \leq \gamma_0.$ Then f is Baire-1 and $\beta(f) \leq \beta_0 \cdot \gamma_0.$ They asked problem 4.7 (still open) in the same paper. Open Problem: Is it true that if $f\in\mathfrak{B}_1(K)$ with $\beta(f)\leq\beta_0 \cdot \gamma_0$ for some countable ordinals β_0 and $\gamma_0.$ then there exists a sequence (f_n) converging pointwise to f so that $\sup_n \beta(f_n) \leq \beta_0$ and $\gamma((f_n)) \leq \gamma_0?$ They showed that the problem has positive answer if $\beta_0 = 1$ (Theorem 5.5) or γ_0 is a limit ordinal (Theorem 4.5). Question: What are the known techniques to construct real-valued functions that satisfy $\sup_n\beta(f_n) \leq \beta_0$ and $\gamma((f_n)) \leq \gamma_0?$ Background and Definitions: Let K be a compact metric space. We say that $f:K\rightarrow \mathbb{R}$ is of Baire 1 if there exists a sequence of continuous functions (f_n) converging to f pointwise. The set $\mathfrak{B}_1(K)$ contains all real-valued Baire 1 functions f on K, both bounded and unbounded. For a Baire 1 function $f:K\rightarrow \mathbb{R}$, its oscillation rank β is defined as follows: For any $\varepsilon>0,$ let $K^0(f,\varepsilon) = K.$ If $K^\alpha(f,\varepsilon)$ is defined for some countable ordinal $\alpha,$ let $K^{\alpha+1}(f,\varepsilon)$ be the set of all those $x\in K^\alpha(f,\varepsilon)$ such that for every open set U containing $x,$ there are two points x_1 and x_2 in $U \cap K^\alpha(f,\varepsilon)$ with $|f(x_1) - f(x_2)| \geq \varepsilon.$ For a countable limit ordinal $\alpha,$ we let $$K^\alpha(f,\varepsilon) = \bigcap_{\alpha^{\prime}<\alpha}K^{\alpha^{\prime}}(f,\varepsilon).$$ The index $\beta_K(f,\varepsilon)$ is taken to be the least α with $K^\alpha(f,\varepsilon) = \emptyset$ if such an α exists, and ω_1 otherwise. The oscillation rank of f is $$\beta_K(f) = \sup\{ \beta_K(f,\varepsilon):\varepsilon>0 \}.$$ If (f_n) is a sequence of real-valued functions on $K,$ let $K^0((f_n),\varepsilon) = K$ for any $\varepsilon>0.$ If $K^\alpha((f_n),\varepsilon)$ has been defined for some countable ordinal $\alpha,$ let $K^{\alpha+1}((f_n),\varepsilon)$ be the set of all those $x\in K^\alpha((f_n),\varepsilon)$ such that for every open set U containing x and any $m\in\mathbb{N},$ there are two integers n_1,n_2 with $n_1>n_2 > m$ and $x' \in U \cap K^\alpha((f_n),\varepsilon)$ such that $|f_{n_1}(x') - f_{n_2}(x')| \geq \varepsilon.$ Define $$K^\alpha((f_n),\varepsilon) = \bigcap _{\alpha' < \alpha}K^{\alpha'}((f_n),\varepsilon)$$ if α is a countable limit ordinal. Let $\gamma_K((f_n),\varepsilon)$ be the least α with $K^\alpha((f_n),\varepsilon) = \emptyset$ if such α exists, and ω_1 otherwise. The convergence index of f is the ordinal $$\gamma_K((f_n)) = \sup\{ \gamma_K((f_n),\varepsilon): \varepsilon>0 \}.$$

Do there exist chess positions that require exponentially many moves to reach?

By "chess" here I mean chess played on an $n\times n$ board with an unbounded number of (non-king) pieces. Some care is needed if you want to generalize some of the subtler rules of chess to an $n\times n$ board, but I will not dwell on this point because the answer to the question I'm interested in should be the same under any reasonable generalization. Namely, does there exist an infinite sequence (A_n, B_n) of pairs of chess positions on an $n\times n$ board such that the minimum number of legal moves required to get from A_n to B_n is exponential in n? Here I allow any legal moves and not only strategically intelligent moves. Technically this question might be classified as an "open problem" (which is illegal on MO) because it was implicitly asked by A. Fraenkel and D. Lichtenstein in "Computing a perfect strategy for $n\times n$ chess requires time exponential in n," J. Comb. Th. A 31 (1981), 199-214. However, I think it is fair game for MO because I'm pretty confident that this has not been looked at much. Fraenkel and Liechtenstein showed that determining whether a given chess position is won for White (with best play) is EXPTIME-complete and asked for the computational complexity of the chess reachability problem ("is B_n reachable from A_n?"). Clearly chess reachability is in NPSPACE = PSPACE, and Hans Bodlaender has shown that it is NP-hard. If the answer to the question I've posed above is "No, it can always

be done with polynomially many moves" then it would solve this problem by showing that chess reachability is NP-complete, because exhibiting the sequence of moves yields a short certificate. If you have some experience with retrograde chess problems and if you've read Hearn and Demaine's lovely book Games, Puzzles, and Computation then you may get the intuition that shuffling chess pieces around is reminiscent of other rearrangement puzzles that have been shown to be PSPACE-complete. However, I've asked both Demaine and Hearn and neither of them saw immediately how to show that chess reachability is PSPACE-complete. [Edit: Searching more carefully through Hearn and Demaine's book, I see that they list this problem in their list of open problems at the end of the book under the name "Retrograde Chess." I didn't notice it before because for some reason that page is not listed in the index under "chess." I can perhaps be blamed for using the name "Retrograde Chess" for this problem because that's what I called it when I first posted this question to USENET way back when. I think that "reachability" is a better name for it.]

The set of numbers $a+b$ such that ma^2+nb^2 is prime

Conjecture: If m,n are coprime it exist a minimal natural number N_{mn} such that: $\{a+b>N_{mn}\mid a,b\in\mathbb N^+\wedge ma^2+nb^2\in\mathbb P_{>2}\} = \{ k > N_{mn} \mid \gcd(k,m+n)=1\}$. Test for $k\leq 10^8$ suggest that $N_{11}=1$. The table below shows the largest minimal N_{mn} for $k\leq 10^5$. In the table 0 stands for $\gcd(m,n)>1$. 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 1 1 1 1 1 1 4 1 1 1 7 1 3 1 1 1 4 1 5 1 1 13 1 1 17 1 2 1 0 1 0 1 0 4 0 1 0 1 0 1 0 31 0 18 0 20 0 10 0 1 0 1 3 1 1 0 1 1 0 1 19 0 10 1 0 3 11 0 6 7 0 1 1 0 9 3 0 1 4 1 0 1 0 8 0 1 0 4 0 1 0 5 0 1 0 5 0 14 0 6 0 1 0 6 5 1 1 1 8 0 16 1 21 1 0 1 1 1 1 0 1 1 22 1 0 1 8 1 18 0 6 4 0 0 0 16 0 20 0 0 0 38 0 1 0 0 0 1 0 6 0 0 0 5 0 16 7 1 4 1 1 1 20 0 1 1 1 1 14 1 0 1 1 1 12 1 19 0 15 1 12 1 8 1 0 19 0 21 0 1 0 10 0 1 0 4 0 19 0 9 0 5 0 13 0 18 0 8 9 1 1 0 4 1 0 1 10 0 17 1 0 1 14 0 1 1 0 3 5 0 6 1 0 1 10 7 0 10 0 0 0 0 1 0 17 0 1 0 1 0 0 0 11 0 1 0 10 0 28 0 0 11 1 1 1 1 1 38 1 1 1 1 0 11 1 16 1 4 1 12 1 6 3 0 1 29 1 12 3 0 0 0 1 0 14 0 0 0 11 0 9 0 0 0 18 0 1 0 0 0 24 0 16 13 1 1 3 5 1 1 1 4 1 1 1 9 0 10 1 20 1 23 1 1 1 1 5 1 1 14 1 0 11 0 1 0 0 0 14 0 16 0 10 0 1 0 33 0 37 0 0 0 1 0 1 15 1 31 0 1 0 0 1 19 0 0 1 0 1 1 0 6 1 0 1 0 0 1 1 0 0 16 4 0 6 0 1 0 1 0 1 0 4 0 20 0 6 0 5 0 9 0 16 0 1 0 1 17 1 18 7 5 1 1 1 9 1 11 1 18 1 33 1 5 0 16 1 7 1 20 1 1 1 18 5 0 0 0 22 0 12 0 0 0 12 0 23 0 0 0 16 0 22 0 0 0 23 0 11 19 1 20 1 14 1 6 1 5 3 1 1 1 1 37 1 9 1 22 0 8 1 5 1 18 1 20 1 0 1 0 0 0 19 0 5 0 6 0 1 0 0 0 7 0 8 0 17 0 8 0 0 21 13 10 0 6 1 0 0 13 0 10 3 0 1 0 0 16 1 0 1 17 0 1 1 0 1 22 1 0 9 0 8 0 15 0 6 0 0 0 1 0 1 0 20 0 5 0 1 0 7 0 1 23 1 1 3 1 1 5 1 18 1 28 1 24 5 1 1 1 1 23 1 8 1 7 0 16 1 24 17 0 0 0 18 0 12 0 0 0 29 0 1 0 0 0 1 0 18 0 0 0 16 0 10 25 1 1 1 6 0 16 1 8 1 0 1 16 1 1 0 1 1 11 1 0 1 1 1 10 0 My question is: are there heuristic reasons for or against the conjecture?

Is there always one integer between these two rational numbers?

It appears that for each integer $k\geq2$, there is always one integer c that satisfies the inequalities below. Can this be proved? $$\frac{3^k-2^k}{2^k-1}<c\leq \frac{3^k-1}{2^k}.$$ Note that for $k\geq2$ the lower bound is always a proper fraction and will never match an integer. Edit 28/1/2018 I have a short proof here on Overleaf. <--- It's done! Edit #28 is perfect! edit It looks like Waring's problem already has a solution. The sequence: https://oeis.org/A060692 "Corresponds to the only solution of the Diophantine equation 3^n = x*2^n + y*1^n with constraint 0 <= y < 2^n." This is equivalent to our $a+c$ for the Waring if statement. Oops, there is no proof that the diophantine equation is always $\leq 2^n.$ Here is a proof sketch of Waring's Here is a brute force function: aplusc[k_] := Module[{c}, c = 1; While[0 < 3^k - 2^k (++c)]; 3^k - 2^k (--c) + c] where we increment c until the calculation becomes negative, then we decrement by one to get c. We recalculate using that c and add them together. A060692(k) equals this value. Closed form: here. The brute force function illustrates the sawtooth pattern. We can also create a(k), b(k), and c(k) using the same module. And we can use b(k) for the proof. Trivially, we can show b$(k) + 1 \leq 2^k.$ edit. Some more information and references: https://oeis.org/A002379 PM

Converse of the Archimedean property of the sphere

In his remarkable book On the Sphere and Cylinder, where he came close to discovering calculus, Archimedes showed that the area of the portion of the sphere contained between a pair of parallel planes cutting the surface depends only on the distance between the planes (see p. 625 of this paper of King). This fact, which has been dubbed Archimedes hatbox theorem, is now a standard exercise in many calculus texts, and is even commemorated on the back of the Fields medal (if you look closely there, you can see the figure below in the background). Conversely, Blaschke showed that the only convex surface with this slab area property is the sphere. Indeed it is a simple exercise in classical differential geometry to check that any smooth convex surface with the slab area property must have constant curvature (Let $A(h)$ be the area trapped between a tangent plane and a parallel plane at distance h, and compute the limit of $A(h)/h$ as $h\to 0$). But can one still characterize the sphere if we fix the distance between the planes: Question: Let $S\subset R^3$ be a convex surface with diameter d. Suppose that for some constant $0<h<d$, the area of the

portion of S trapped between every pair of parallel planes separated by the distance h is constant, whenever both planes intersect S. Does it follow then that S is a sphere? A convex surface is the boundary of a compact convex set with interior points, and its diameter is the distance between its farthest points in the ambient space. Although this is known to be an open problem, I am not aware if it has been explicitly mentioned anywhere. Addendum: See this question for a closely related problem on plank invariant measures for convex planar's domains, and more references in this area.

Plank invariant measures on convex bodies

Let $K\subset R^2$ be a convex body, i.e., a compact convex set with interior points. A plank P is the region between a pair of parallel lines in R^2. Let us say that P intersects K properly provided that both boundary lines of P intersect K. Question: Let $K\subset R^2$ be a convex body with diameter d. Suppose there exists a measure μ on K such that $\mu(P\cap K)$ is constant for all planks of some fixed width $0<h<d$ which properly intersect K. Must K then be a disk? A disk $D\subset R^2$ does indeed admit such a measure. Let $S\subset R^3$ be a sphere with D as an equatorial disk, and μ be the measure on D induced by the projection of S (see the picture below which is from this paper of Kupavskii and Pach). Then μ will be plank invariant due to the Archimedes hatbox theorem. The motivation for the above question is that a positive answer here would yield a positive answer to this earlier question, on the Converse of the Archimedean property of the sphere, as follows. Suppose that there exits a convex surface $S\subset R^3$ with the Archimedean slab invariant area property mentioned in the earlier question. Then the projection of S into any plane would yield a convex body with the plank invariant property with respect to the induced measure. Hence the projection would be a disk, if the answer to the above question were yes, which would in turn imply that S is a sphere (it is well-known that the sphere is the only convex surface with round projections). For some results in the direction of the above problem see this paper of Gardner. Another nice paper discussing some relevant background and questions is the expository paper of King in the Monthly. More references can be found in the recent paper of Kupavskii and Pach mentioned above. Also see the answer to this related question asked earlier, and another similar question which has remained unanswered. Questions of this type have connections to Tarski's plank problem and an open question of Bang.

Converse to Euclid's fifth postulate

There is a fascinating open problem in Riemannian Geometry which I would like to advertise here because I do not think that it is as well-known as it deserves to be. Euclid's famous fifth postulate, or more precisely Playfair's version of it, states that, in the Euclidean plane, through every point outside a line ℓ there passes one and only one line which does not intersect ℓ. Question: Is the Euclidean plane the only complete Riemannian manifold homeomorphic to R^2 which satisfies the fifth postulate, i.e., through any point outside a complete geodesic γ there passes one and only one complete geodesic which does not intersect γ? In other words, does the fifth postulate force the curvature to be zero? The reason this is interesting, or historically significant, is that it was the attempts to reduce the fifth postulate to the other axioms of Euclid, throughout the middle ages, which eventually led to the discovery of non Euclidean geometries and the notion of curvature by Gauss and Riemann. This problem appears to be originally due to Burns and Knieper in 1991: see the survey paper by Burns and Matveev, which also includes other nice problems on geometry of geodesics. The problem is also mentioned in papers of Croke, and Bangert and Emmerich, and has been studied most recently by Ge, Guijarro, and Solorzano.

Intrinsic vs Extrinsic geometry of convex surfaces

By Alexandrov's isometric embedding theorem, any locally convex metric prescribed on the sphere admits a realization as a convex surface in Euclidean 3-space, which, by Pogorelov's rigidity result, is unique up to an isometry of the ambient space. Thus, the intrinsic geometry of a convex surface completely determines its extrinsic geometry, and in principle it should be possible to describe all geometric quantities in terms of the intrinsic metric. On the other hand, Alexandrov's proof is not constructive, and does not provide any hints as to how one might be able to do this. Hence my first question is: Question 1: Is there any way to compute, recognize, or characterize intrinsically any of the geometric quantities or features of a convex surface which are not invariant under local isometric deformations, e.g., mean curvature, principal directions, principal curvatures, or umbilic points? I recognize this might be too much to ask, because the procedures which the above question asks for would somehow need to take into account the whole metric, not just a neighborhood of a point. So let me try to make things a bit more concrete and maybe a little more accessible. It is well known that any (smooth) convex surface must have at least one umbilic, i.e., a point where the principal curvatures are equal (if not then the direction of the larger principal curvature yields a nonvanishing line field on the surface which violates the Poincare-Hopf index theorem). Can one prove this without reference to the ambient space, or quantities that we only know how to compute extrinsically: Question 2: Is it possible to prove the existence of an umbilic point of a smooth convex surface in a purely intrinsic way? If so, can one also find or approximate the location of the umbilics? One motivation behind this questions is the famous conjecture of Caratheodory, which states that each convex surface must have at least two umbilics. The extrinsic or local approaches to this problem have always been problematic. Adendum: As Robert Bryant correctly points out below, the topological argument for the existence of at least one umbilic described above is really intrinsic and independent of the notion of principal directions. So the main point of Question 2 is its second part, i.e., to somehow get a handle on the location of the umbilic. See also this related question.

What is an umbilic point of a convex polyhedron?

An umbilic point of a smooth (C^2) convex surface in Euclidean 3-space is a point where the principal curvatures are equal. Is there some good way to generalize this notion to convex polyhedra? See this earlier question, specially the comments by Igor Rivin and Ivan Izmestiev for the motivation behind the current question. First, what do I mean by "good"? Here are some requirements that come to mind (which may be negotiable): It is not necessary for the notion of umbilic to be defined for all convex polyhedra but it would be enough if it is well-defined for generic polyhedra, or a class of polyhderda which is dense in the space of all convex polyhedra, and possibly open as well. Each convex polyhedron (or each polyhedron in the generic subclass) should have at least one umbilic point. It would be better if each polyhedron had at least two umbilics, or otherwise there was a notion of index associated to each umbilic so that the sum of the indices was constant for all polyhedra (in parallel with the index formula for the singularities of a line field on a sphere). It would be reassuring if there were some convex polyhedra with exactly two umbilics. (Bonus) Ultimately it would be nice if this notion were stable as a family of convex polyhedra converges to a smooth convex surface, but this can be set aside for now. Question: Does there exist a notion of umbilic point for convex polyhedra which would satisfy the first four requirements listed above? As was suggested by Ivan Izmestiev, maybe one should consider the Gauss image around vertices of the polyhedron. More precisely, consider the outward unit normals at the faces around a vertex. These normals form the vertices of a convex spherical polygon whose edges are geodesic arcs which join a pair of normals if and only if those normals correspond to adjacent faces of the polyhedron. So a vertex would be considered umbilic if its spherical image is somehow "circular" or relatively round (as is the case in the smooth case). Perhaps a useful guide here could be the generalized four vertex theorem for convex (spherical) polygons; see for instance Section 21 of Igor Pak's Lecture Notes and the corresponding papers of Serge Tabachnikov cited there. I first heard about the question in the title when Brian White asked me that in 2010. My idea back then was to consider the class of convex polyhedra with quadrilateral faces, and define an umbilic point as a vertex with degree different from 4. It is a simple exercise to show, via Euler's formula, that all convex polyhdera with quadrilateral faces must have at least 8 umbilics in this sense. The intuition behind this definition was the notion of "circular planar quadrilateral meshes", or "circular nets" which are discrete analogues of principal curvature lines. See for instance the book of Bobenko and Suris. This then was a purely topological candidate, and I did not get much chance to think about it more since then. Perhaps it might be more fruitful to consider geometric alternatives mentioned above, or some kind of a hybrid.

Conjecture: The number of points modulo p of certain elliptic curve is p or $p+2$ for p of form $p=27a^2+27a+7$

Numerical evidence suggests a conjecture that the number of points of certain elliptic curve over $\mathbb{F}_p$ is either p or $p+2$ for p of certain form. Let p be prime of the form $p=27a^2+27a+7$ and (a/b) denote the Kronecker symbol. For integer k nonzero modulo p define $E_k / \mathbb{F}_p : y^2=x^3+2k^3$. E_k is the quadratic twist of $y^2=x^3+2$. Conjecture 1: $\#E(\mathbb{F}_p)=p+1 + (2k^3 / p)$. In other words for p of the given form $\#E(\mathbb{F}_p)$ is either p or $p+2$. Is Conjecture 1 true? Example sage session with 200 bit p sage: a=2^100+8;p=27*a^2+27*a+7;k=3;Kp=GF(p);E=EllipticCurve([Kp(0),Kp(2*k^3)]) sage: o=E.order();o2=p+1+kronecker(2*k^3,p);o==o2 True

Equilaterally triangulated surfaces with prescribed boundary

There is a problem in Richard Kenyon's list (Wayback Machine) which I would like to post here, because although I have thought about it from time to time, I have not been able to make the slightest progress on it: Question: "Given a closed polygonal path p in R^3 composed of unit segments, is there an immersed polygonal surface whose faces are equilateral triangles of edge length 1, spanning p?" The condition that the configuration is an "immersed" surface means that the whole configuration may be parametrized by a continuous locally one-to-one mapping from a compact connected 2-dimensional manifold with boundary into R^3. In other words at most two triangles may share an edge, and triangles sharing a vertex form an embedded topological disk, but two triangles which do not share an edge or a vertex may intersect. I cannot answer the question even for the case where p is a quadrilateral. Has there been any partial results for this problem?

On statistical bases in Banach spaces

Let K be a subset of the positive integers $\mathbb{N}$. For each $n\in \mathbb{N}$, K_{n} denotes the set $\{k\in K: k\leq n\}$ and $|K_{n}|$ denotes the number of the elements in K_{n}. The natural density of K is defined by $$\delta(K)=\lim_{n\rightarrow \infty}\frac{|K_{n}|}{n}.$$ A sequence $(x_{k})_{k}$ in a Banach space X is said to be norm statistically convergent to $x\in X$ if $\delta(\{k\in \mathbb{N}:\|x_{k}-x\|\geq \epsilon\})=0$ for every $\epsilon>0$. It is natural to define a series $\sum_{k=1}^{\infty}x_{k}$ to be norm statistically convergent to $x\in X$ by $(s_{n})_{n}=(\sum_{k=1}^{n}x_{k})_{n}$ to be norm statistically convergent to x. We say that a sequence $(x_{k})_{k}$ in a Banach space X is a statistical basis for X if, for each $x\in X$, there exists a unique $(a_{k})_{k}$ such that the series $\sum_{k=1}^{\infty}a_{k}x_{k}$ norm statistically convergent to x. Clearly, statistical basis is a generalization of the notion of Schauder basis. Question: For each n, we can define a linear functional f_{n} in X by $f_{n}(x)=a_{n}$. If $(x_{k})_{k}$ is a Schauder basis, we know that f_{n} is continuous. However, if $(x_{k})_{k}$ is a statistical basis for X, is f_{n} continuous?

Portability of Thompson theorem about solvability to Moufang loops

Say we have a finite Moufang Loop Q, $|Q|<\infty$. There is a theorem proved by Thompson that states: Group G, $|G|<\infty$ is solvable $\iff$ $\forall a, b \in G$, $\langle a, b\rangle$ is solvable. My question is: can we translate the theorem to the finite Moufang loops (maybe with some extra constraints)? The statement is reasonable because it is well-known that every pair of Moufang loop's elements forms a group structure (Moufang's theorem). What is interesting, Feit-Thompson theorem about solvability of finite groups with odd order translates to the Moufang loop case. The proof can be found here. There is an idea to translate the task to the case of $U(R)$, where R is alternative algebra, $1 \in R$.

Two questions on "Table problem on $\Bbb S^2$"

The following conjecture is known as "Table problem on $\Bbb S^2$" Conjecture (Table problem on $\Bbb S^2$): Suppose $x_1, x_2,x_3,x_4 \in\Bbb S^2 \subseteq \Bbb R^3$ are the vertices of a square that is inscribed in the standard 2-sphere, and let $h : \Bbb S^2\to \Bbb R$ be a smooth function. Then there exists a rotation $\rho\in \rm{SO}(3)$ such that $h(\rho(x_1)) =\cdots= h(\rho(x_4))$. Question 1: What is the meaning of "standard 2-sphere"? topological 2-sphere or geometrical? Question 2: Is this conjecture open still?

A conjecture regarding prime numbers

For $n,m \geq 3$, define $ P_n = \{ p : p$ is a prime such that $ p\leq n$ and $ p \nmid n \}$. For example : $P_3= \{ 2 \}$ $P_4= \{ 3 \}$ $P_5= \{ 2, 3 \}$, $P_6= \{ 5 \}$ and so on. Claim: $P_n \neq P_m$ for $m\neq n$. While working on prime numbers I formulated this problem and it has eluded me for a while so I decided to post it here. I am not sure if this is an open problem or solved one. I couldn't find anything that looks like it. My attempts haven't come to fruition though I have been trying to prove it for a while. If m and n are different primes then it's clear. If $m \geq 2n$, I think we can find a prime in between so that case is also taken care of. My opinion is that it eventually boils down to proving this statement for integers that share the same prime factors. My coding is kind of rusty so would appreciate anybody checking if there is a counterexample to this claim. Any ideas if this might be true or false? Thanks. PS: I asked this question on mathstackexchage and somebody recommended I post it here as well. Here is the link to the original post https://math.stackexchange.com/questions/2536176/a-conjecture-regarding-prime-numbers

Asymptotic form of pdf of Escape Time of arithmetic fBm

I am trying to apply the Girsanov formula and Doobs optional sampling theorem to obtain an asymptotic form of first passage density of an fbm process with drift, but the answer i am getting seems strange, it does not match the brownian motion case result as well as i assumed it would. I am seeking help in debugging these computations. I am also very much interested in learning about analytical ways of verifying this result. Thank You Some known results The first passage density of Brownian motion case is given by the following theorem. Theorem: Let the arithmetic Brownian motion process $X \left(t\right)$ be defined by the following Brownian motion driven SDE \begin{equation} \mbox{d}X \left(t\right) = a \mbox{d}t + b \mbox{d}{W}\left(t\right). \end{equation} with initial value X_0. Let $\tau =\inf \left(u |X(u) \le B\right)$ denote the first passage time for the barrier $X_0 < B$. Then the first passage time τ is distributed as Inverse Gaussian Distribution \begin{equation} \tau \sim IG\left(\frac{B - X_0}{a}, \frac{\left(B - X_0\right)^2}{b^2}\right),\label{abmFirstPassageDist} \end{equation} and for $t > 0$ the pdf of τ is \begin{equation} f(t) = \sqrt{\frac{(B - X_0)^2}{2 \pi b^2 t^3}} \exp\left[-\frac{ \left(at - B + X_0\right)^2}{2 b^2 t}\right]\label{abmFirstPassageDensity}. \end{equation} The Girsanov formula for fBm Let $B^H \left(t\right)$ denote fractional brownian motion with mean 0 and variance t^{2H}, for all $H \in \left(0, 1\right)$ defined on $\left(\Omega, \mathcal{F}, \mathbb{P}\right)$. Let a be a scalar. Define a new probability measure $\mathbb{Q}$ on $\left(\Omega, \mathcal{F}\right)$ via the Radon Nikodym derivative with respect to $\mathbb{P}$ \begin{equation} \frac{\mbox{d}{\mathbb{Q}}}{\mbox{d}{\mathbb{P}}} = \exp\left\{a M_T - \frac{1}{2}{a}^2 \langle M, M\rangle_T \right\}\label{girsanovRadonNikodymDerivativeWithInnerProduct} \end{equation} where \begin{equation} M_T = \frac{1}{2 H \Gamma \left(\frac{3}{2} - H\right) \Gamma \left(H +

\frac{1}{2}\right)} \int_0^T \left(s\left(T - s\right)\right)^{\frac{1}{2} - H} \mbox{d}{{B_s}^H}. \end{equation} The process M_T is a martingale with independent increments, zero mean and variance function $c^2 T^{2 - 2H}$ where \begin{equation}\label{c} c = \sqrt{\frac{\Gamma\left(\frac{3}{2} - H\right)}{2 H \left(2 - 2H\right)\Gamma\left(H + \frac{1}{2}\right)\Gamma\left(2 - 2H\right)}}. \end{equation} Then the process defined, for all $t \in \left[0, T\right]$, by $B^H \left(t\right) + a t$ is the standard $\mathbb{Q}$-fractional Brownian motion on $\left[0, T\right]$. In other words, under probability measure $\mathbb{Q}$, $B^H \left(t\right)$ restricted to $t \in \left[0, T\right]$ is distributed as an arithmetic fractional Brownian motion with drift a. A proof of the Girsanov formula for fractional Brownian motion can be found in Norros's paper, where the term the fundamental martingale is also coined for the process M_t. It's noteworthy that using the variance of M_t, Radon Nikodym Derivative can also be re-written as \begin{equation} \frac{\mbox{d}{\mathbb{Q}}}{\mbox{d}{\mathbb{P}}} = \exp\left\{a M_T - \frac{1}{2}{a}^2 c^2 T^{2 - 2H} \right\}.\label{girsanovRadonNikodymDerivative} \end{equation} corollary Let $X\left(t\right) = b B^H \left(t\right)$ be an arithmetic fractional brownian motion with volatility b, for all $H \in \left(0, 1\right)$ defined on $\left(\Omega, \mathcal{F}, \mathbb{P}\right)$. Let a be a scalar. Define a new probability measure $\mathbb{Q}$ on $\left(\Omega, \mathcal{F}\right)$ via the Radon Nikodym derivative with respect to $\mathbb{P}$ \begin{equation} \frac{\mbox{d}{\mathbb{Q}}}{\mbox{d}{\mathbb{P}}} = \exp\left\{\frac{a}{b} M_T - \frac{1}{2}\frac{a^2}{b^2} c^2 T^{2 - 2H}\right\}.\label{scaledGirsanovRadonNikodymDerivative} \end{equation} Then the process defined, for all $t \in \left[0, T\right]$, by $Z \left(t\right) = X \left(t\right) + a t$ is an arithmetic $\mathbb{Q}$-fractional Brownian motion process on $\left[0, T\right]$ with volatility b. In other words, under probability measure $\mathbb{Q}$, $X\left(t\right)$ restricted to $t \in \left[0, T\right]$ is distributed as an arithmetic fractional Brownian motion with drift a and volatility b. Proposition Let $B^H \left(t\right)$ denote scaled fractional brownian motion with mean 0 and variance $b^2 t^{2H}$, for all $H \in \left(0, 1\right)$ with respect to measure $\mathbb{P}$. Define $\tau_k = \inf \left\{t \ge 0 : B^H \left(t\right) = k\right\}$ for $k > 0$. Then the conditional mean and variance of M_t given B_t are \begin{equation} E\left(M_t | B^H \left(t\right) = k \right) = {t^{1-2H} k \over b} \end{equation} and \begin{equation} \hbox{Var}\left(M_t | B^H \left(t\right) = k\right) = t^{2-2H}\left(c^2-1\right). \end{equation} Proof Both $B^H \left(t\right)$ and M_t have mean zero, the variance of $B^H \left(t\right)$ is $b^2 t^{2H}$, the variance of M_t is $c^2 T^{2 - 2H}$, and their covariance bt, can be derived similarly to, as in Proposition 3.2, in Norros's paper. Hence the correlation coefficient ρ between M_t, $B^H \left(t\right)$ is $1/c$. Therefore, using elementary results for the bivariate normal distribution, we find \begin{eqnarray} E\left(M_t | B^H \left(t\right) = k \right) &=& {\rho \sigma_{M_t}\over \sigma_{B^H \left(t\right)}}k\\\nonumber &=& {t^{1-2H} k \over b}\nonumber \end{eqnarray} and \begin{eqnarray} \hbox{Var}\left(M_t | B^H \left(t\right) = k\right) &=& {\sigma^2}_{M_t}\left(1 - \rho^2\right) \\\nonumber &=& t^{2-2H}\left(c^2-1\right).\nonumber \end{eqnarray} The Derivation Attempt By Doob's optional sampling theorem (justified by the uniform integrability of the martingale \begin{equation} \exp\left\{\frac{a}{b} M_T - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_T\right\}\nonumber \end{equation} on $\left[0, T\right]$ and the fact that $\left\{\tau_k \le T \right\} \in \mathcal{F}_{\tau_k} \cap \mathcal{F}_{T} = \mathcal{F}_{\tau_k \bigwedge T} \subseteq \mathcal{F}_T$), \begin{equation} \mathrm{E}\left[\left.\exp\left\{\frac{a}{b} M_T - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_T\right\} \right| \mathcal{F}_{\tau_k \bigwedge T}\right] = \exp\left\{\frac{a}{b} M_{\tau_k \bigwedge T} - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_{\tau_k \bigwedge T}\right\}. \end{equation} Therefore, \begin{eqnarray} \mathbb{P}^{a,T}\left[\tau_k \in (t,t+dt)\right] &=& \mathbb{E}^{a,T} \left[1_{\left\{\tau_k \in (t,t+dt)\right\}} \right]\\ \nonumber &=& \mathbb{E}\left[\exp\left\{\frac{a}{b} M_T - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_T\right\}1_{\left\{\tau_k \in (t,t+dt)\right\}}\right] \end{eqnarray} by Corollary above \begin{eqnarray} \nonumber &=& \mathbb{E}\left[\left.\mathbb{E}\left[\exp\left\{\frac{a}{b} M_{\tau_k \bigwedge T} - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_{\tau_k \bigwedge T}\right\} \right|{\cal F}^{B^H}_{\tau_k\wedge T}\right]1_{\left\{\tau_k \le T\right\}}\right]\\ \nonumber &=& \mathbb{E}\left[\exp\left\{\frac{a}{b} M_{\tau_k} - \frac{1}{2}\frac{a^2}{b^2} \langle M, M\rangle_{\tau_k}\right\}1_{\left\{\tau_k \le T\right\}}\right]\\ \end{eqnarray} by Doob's sampling theorem \begin{eqnarray} \nonumber &=& \mathbb{E}\left[\exp\left\{\frac{a k}{b^2}{\tau_k}^{1-2H} - \frac{1}{2}\frac{a^2}{b^2} {\tau_k}^{2-2H}\left(c^2 - 1\right)\right\}1_{\left\{\tau_k \le T\right\}}\right]\\ \end{eqnarray} by propostion above \begin{eqnarray} \nonumber &=& \int_0^T \exp\left[\frac{a k t^{1-2H}}{b^2} - \frac{1}{2}\frac{a^2 t^{2 - 2H}}{b^2} \left(c^2 - 1\right)\right] \mathrm{P}\left[\tau_k \in \mbox{d}{t}\right]. \end{eqnarray} On the other hand, $\left\{B^H \left(t\right) + a t\right\}_{t \in \left[0, T\right]}$ is a scaled fractional Brownian motion under $\mathbb{P}^{a,T}$, so \begin{equation} \mathbb{P}^{a,T} \left[\tau_k \le T\right] = \mathbb{P}\left[\hat{\tau_k} \le T\right], \end{equation} where $\hat{\tau_k}$ is the first hitting time of the level k of the scaled fractional Brownian motion with drift a. Using the formula for asymptote of the first passage density of fBM without drift due to Molchan, it follows immediately that the long-time form of the first passage time density for fBm with drift is given by \begin{eqnarray} f\left(t\right) &=& \exp\left[\frac{a k t^{1-2H}}{b^2} - \frac{1}{2}\frac{a^2 t^{2 - 2H}}{b^2} \left(c^2 - 1\right)\right] t^{H-2}.\label{firstPassageDensityArithmeticFbm} \end{eqnarray} It is noteworthy that C^2 has a minimum at $H =\frac{1}{2}$, where $c^2 = 1$. Verification Against Brownian motion case Upon substituting $H = \frac{1}{2}$ in c^2 evaluates to 1, and the function reduces to \begin{eqnarray} f_{H = \frac{1}{2}}\left(t\right) &=& \exp\left[\frac{a k}{b^2}\right] t^{-\frac{3}{2}}. \end{eqnarray} This seems a bit off as according to "Brownian motion and stochastic calculus" books, it should be \begin{eqnarray} f'_{H = \frac{1}{2}}\left(t\right) &=& \exp\left[\frac{a k}{b^2} - \frac{a^2}{2b^2}t \}\right] t^{-\frac{3}{2}}. \end{eqnarray} The presence of $c^2 - 1$ seems to prevents a perfect match with the Brownian motion case.

The difference between two coprime semiprimes

Conjecture: Any positive integer can be written as the difference between two coprime semiprimes. Tested up to 1,000,000. See also: https://math.stackexchange.com/questions/2579578/the-difference-of-two-coprime-composites I'm not surprised that there are heuristics backing up the conjecture, but think it would be strange if the proof was so far away when the question above had an easy answer.

If $a^3+b^3+c^3=N$, then $x^3+y^3+z^3+t^3 = N$ in infinitely many ways?

It is well-known that, $$a^3+b^3+c^3 = N\tag1$$ for $N=1,\,2$ is solvable in the integers in infinitely many ways . However, it is an open question (but is conjectured) that if for general N it has a solution, then it must have infinitely many. I'd like to propose a variant, Conjecture: If $a^3+b^3+c^3=N$, then $x^3+y^3+z^3+t^3 = N$ in infinitely many ways. Part I: Use the identity, $$x^3+y^3+z^3+t^3 = (a^3+b^3+c^3)\big(p^2+(a+b)cq^2\big)^3$$ where, $$\begin{aligned} t &= a p^2 - c^2 p q + b (a + b) c q^2 \\ x &= b p^2 + c^2 p q + a (a + b) c q^2\\ y &= c p^2 + (a^2 - b^2) p q\\ z &= -(a^2 - b^2) p q + (a + b) c^2 q^2\end{aligned}$$ Part II: Solve the Pell equation, $$p^2+(a+b)cq^2 = 1\tag2$$ This is the tricky part since we require $(a+b)c<0$. Perusing through S. Huisman 15254 solutions, I find that all his solvable N have solutions where both a,b are negative, or c is negative. Of course, (2) can then be easily solved as a Pell equation. Q: If (1) has a solution in positive integers, then how do we prove that implies a subsequent solution where one or two of the variables are negative? P.S. The second solution may be huge, $$4^3+ 4^3+ 7^3 =-17863863023^3+ 13242033973^3+ 15005424841^3 = 471$$ but it guarantees infinitely many solutions to (2).

A group action of the Heisenberg group with special symmetries

Suppose we look at the Heisenberg group H_{d} as a matrix group of upper triangular matrices over the ring $\mathbb{Z}/d\mathbb{Z}$. You can even choose d to be prime if you want. A natural irrep of H_{d} acting on $\mathbb{C}^{d}$ maps the group elements into the "shift" and "phase" operators, plus roots of unity. More specifically, the two natural generators map the orthonormal basis vectors from $j \to j+1\mod d$, and the Fourier transform of that operation, plus overall phases by roots of unity. The question is this: Can you find a unit vector v such that $|(v,U_g v)| = c$ for all g not in the center of $H_{d}\ ?$ One can solve for the constant: $c=\frac{1}{\sqrt{d+1}}$. Numerics suggests that these vectors exist in all the dimensions < 67, hence they may exist in every dimension, but the form of the vectors contains no (obvious) hint as to how to prove this. This problem seems extremely truculent and any help is greatly appreciated!

Volumes of sets of constant width in high dimensions

Background The n-dimensional Euclidean ball of radius $1/2$ has width 1 in every direction. Namely, when you consider a pair of parallel tangent hyperplanes in any direction the distance between them is 1. There are other sets of constant width 1. A famous one is the Reuleaux triangle in the plane. The isoperimetric inequality implies that among all sets of constant width 1 the ball has largest volume. Let's denote the volume of the n-ball of radius $1/2$ by V_n. The question Is there some $\varepsilon >0$ so that for every $n>1$ there exist a set K_n of constant width 1 in dimension n whose volume satisfies $\mathrm{vol}(K_n) \le (1-\varepsilon)^n V_n$. This question was asked by Oded Schramm who also asked it for spherical sets of constant width r. A proposed construction Here is a proposed construction (also by Schramm). It will be interesting to examine what is the asymptotic behavior of the volume. (And also what is the volume in small dimensions 3,4,...) Start with $K_1=[-1/2,1/2]$. Given K_n consider it embedded in the hyperplane of all points in R^{n+1} whose $(n+1)$-th coordinate is zero. Let K^+_{n+1} be the set of all points x, with nonnegative $(n+1)$-th coordinate, such that the ball of radius 1 with center at x contains K_n. Let K^-_{n+1} be the set of all points x, with nonpositive $(n+1)$-th coordinate, such that x belongs to the intersection of all balls of radius 1 containing K_n. Let K_{n+1} be the union of these two sets K^-_{n+1} and K^+_{n+1}. Motivation Sets of constant width (other than the ball) are not lucky enough to serve as norms of Banach spaces and to attract the powerful Banach space theorist to study their asymptotic properties for large dimensions. But they are very exciting and this looks like a very basic question. References and additional motivation In the paper: "On the volume of sets having constant width" Isr. J Math 63(1988) 178-182, Oded Schramm gives a lower bound on volumes of sets of constant width. Schramm wrote that a good way to present the volume of a set $K \subset R^n$ is to specify the radius of the ball having the same volume as K, called it the effective radius of the set K and denote it by $\operatorname{er} K$. Next he defined r_n as the minimal effective radius of all sets having constant width two in R^n. Schramm proved that $r_n \ge \sqrt {3+2/(n+1)}-1$. He asked if the limit of r_n exists and if r_n is a monotone decreasing sequence. Our question is essentially whether r_n tends to 1 as n tends to infinity. In the paper: O. Schramm, Illuminating sets of constant width. Mathematika 35 (1988), 180--189, Schramm proved a similar lower bound for the spherical case and deduced the best known upper bound for Borsuk's problem on covering sets with sets of smaller diameter.

What is the smallest sphere whose surface includes 100 integer points?

Let $S(r)$ be the surface of the origin-centered sphere in $\mathbb{R}^3$. A point is an integer point if all its coordinates are integers. What is the smallest radius r_n such that $S(r_n)$ includes $\ge n$ integer points? What is the growth rate of r_n with respect to n? Is there an algorithm that could compute r_n for a specific given n? It is known that rational points (all coordinates rational) are dense on $S(1)$: see, e.g., the MO question Rational points on a sphere in $\mathbb{R}^d$. One possible approach is via rational points of bounded height. The height of a rational a/b in lowest terms is max$(|a|,|b|)$, and the height of a rational point is the max of the heights of its coordinates. Rationals of height ≤ 2048 on sphere. Image due to Stefan Kohl in this answer. Choose an appropriate $h_\max$, perhaps using an estimate of the number of rational points of height at most $h_\max$ on $S(1)$. Then scale all coordinates by the LCM of the points' denominators. For example, for $h_\max=10$, scaling by $2^3 \cdot 3^2 \cdot 5 \cdot 7 = 2520$ would suffice to clear all denominators, so that $S(2520)$ includes all those points at integer coordinates. But this would not necessarily result in the minimum r_n for a given n. It would likely be better to use rational points that result in a small LCM. Exact calculations on a sphere (for example, computing Voronoi diagrams on a sphere) often need integer points of bounded size. Update. The exact answer to the question in the title, due to Dap and Gerhard Paseman, is that a sphere of radius $\sqrt{74} \approx 8.6$ includes 120 integer points on its surface, and smaller spheres include fewer than 100 points.

Open problems in the theory of manifolds relating to construction

A while ago I stumbled across a paper of Thurston: Some Simple Examples of Symplectic Manifolds, where Thurston constructs closed symplectic manifolds with no Kaehler structure. My question is: What are the most rewarding and beautiful (potential) manifolds that one might seek to construct, that have not been constructed thus far? (Does there exist [insert]?). Obviously potential constructions are not restricted to manifolds , however I am mostly interested in constructions of manifolds or spaces in the most current and/or new areas of research in geometry and topology. I would also be interested in conjectures (interconnected or otherwise) relating to manifolds that can be resolved via constructions, what constructions?

What is known about the relationship between Fermat's last theorem and Peano Arithmetic?

As far as I know, whether Fermat's Last Theorem is provable in Peano Arithmetic is an open problem. What is known about this problem? In particular, what is known about the arithmetic systems $PA + \text{Fermat's Last Theorem}$ and $PA + \lnot \text{Fermat's Last Theorem}$? Note in particular that if $PA \vdash \text{Fermat's Last Theorem}$, the first system will just be PA and the second system with be inconsistent. If FLT is independent of PA, then both will be consistient systems distinct from PA. $PA \vdash \lnot \text{Fermat's Last Theorem}$ is not possible, since PA and Fermat's last theorem are both true in $\mathbb N$.

Open problems concerning Araujo's biseparating maps

Araujo stated the following four open questions at the end of his paper, page 518 and $519.$ Question $1:$ Assume that there exists a biseparating map $T:A^n(\Omega:E)\to A^m(\Omega',F)$ which is not linear. Can we deduce that the support map $h:\Omega'\to\Omega$ is a diffeomorphism of class $n?$ Problem $2:$ Suppose that $C^\infty(\Omega,E)$ is the space of E-valued functions which are of class C^∞ in $\Omega,$ and that $C^\infty(\Omega',F)$ is defined in a similar way. Describe the linear biseparating maps from $C^\infty(\Omega,E)$ onto $C^\infty(\Omega',F).$ Must such map be continuous? Problem $3:$ Let Ω and Ω' be unbounded open subsets of $\mathbb{R}^p$ and $\mathbb{R}^q$ respectively. Describe the linear biseparating maps from $C^n_*(\Omega,E)$ onto $C^m_*(\Omega',F).$ Problem $4:$ Determine all subspaces $A(\Omega,E)\subseteq A^n(\Omega,E)$ and $B(\Omega',F)\subseteq A^m(\Omega',F)$ such that the existence of a linear biseparating map from $A(\Omega,E)$ onto $B(\Omega',F)$ implies that E and F are isomorphic as Banach spaces. What is the status of these questions? Any progress on each of them? If yes, any reference is appreciated. Definitions: Let $\Omega\subseteq \mathbb{R}^p$ be an open subset and E be a Banach space. Denote $C^n(\Omega,E)$ the space of E-valued functions f on Ω that are of class $C^n.$ $T:C^n(\Omega,E)\to C^m(\Omega',F)$ is called biseparating map if T is bijective and $$\|Tf\| \|Tg\|=0 \text{ if and only if }\|f\|\|g\|=0$$

Discriminant of numerator of inverse logarithmic derivative operator iteration

Let $T:\mathbb Q(x)\to \mathbb Q(x)$ be the operator of inverse logarithmic derivative, i.e. $$Tf=\frac{f}{f'}.$$ Define $$p_n(x)=T^n\left(x-\frac{x^2}{2}\right).$$ Let $f_n(x) \in \mathbb Z[x]$ be the numerator of $p_n(x)$, taken with positive leading term. The sequence D_n of discriminants of our polynomials starts with $$\begin{aligned} D_0&=4,\\ D_1&=4,\\ D_2&=4,\\ D_3&=-256=2^8,\\ D_4&=2^{32}5^2,\\ D_5&=2^{128}5^6331^2, \\D_6&=2^{512}5^{20}331^646599695357^2.\\ \end{aligned} $$ Is it true that we always have $D_n=\pm a_n^2$ for some integer a_n? What else can be said about the arithmetic properties of a_n? For example, is it true that for all $n \geq 2$ we have $\nu_2(D_n)=2^{2n-3}$?

A "conjectured" concentration inequality for operators, probably related with random matrix theory

I am working on some open problem. And I have reduced the original problem to the "conjecture" (actually I am not familiar with random matrix theory or other fields that may have such a result) as follows. Consider a random variable X supported on $\mathbb{R}^{d}$ with distribution P_X. Assume we have constructed a cover of $\mathbb{R}^{d}$ denoted as $\{\Lambda(\omega):\omega\in\Omega\}$, where Ω is a finite set. We then make Ω into some probability space and introduce an extra r.v. σ that takes value in Ω. Now since we have (or not, why?) $$ \mathbb{E}_{\sigma}\int_{\Lambda(\sigma)}XX^{T}dP_{X} = \mathbb{E}_{X}[XX^{T}] $$, there should exist some constant $\lambda >0$, such that the following operator inequality is true with probability (in the order of positive semi-definiteness) $$ P_{X}(\Lambda(\sigma))\mathbb{E}_{X}[XX^{T}] - \lambda{I} \preceq \int_{\Lambda(\sigma)}XX^{T}dP_{X}\preceq P_{X}(\Lambda(\sigma))\mathbb{E}_{X}[XX^{T}] + \lambda{I} $$ From my perspective, the existence may be easy as we could somehow add some additional assumptions on P_X to assert the "boundedness" of XX^{T}. Thus we could take λ larger than the upper bound. Could anyone provide some reference or hints relevant to this problem? That will help a lot.

The Krzyż Conjecture

What is the state of the Krzyż Conjecture? It states for that for all $f:\mathbb{D}\to \bar{\mathbb{D}}$ holomorphic and non-vanishing, the coefficients a_n in the power series of f are at most $2/e$ in absolute value seen from the maximal function $$f(z)=e^{\frac{z^n+1}{z^n-1}}$$ I have read The Krzyż Conjecture Revisited where the authors (in 2014) say the problem is open for coefficients $n>5$. A paper by S. Krushkal claims to have proved it, but in the former paper Krushkal's work is mentioned: Krushkal's unpublished preprint, in spite of some gaps, contains a wealth of geometric and analytic ideas which may be useful for a further study of problems of this type I could not spot any obvious holes but it has yet to be published in a reputable journal as far as I know, so I wonder if someone with a more penetrating and experienced eye could verify or point the "gaps".

An upper bound for a vector with given norm 1 and norm 2

Suppose $X = (x_1, \ldots , x_n)$ is given and we know that x_i's are nonnegative, $\sum_{i=1}^n x_i = n$ and $\sum_{i=1}^n x_i^2 = m $. Just by this information, is it possible to find a vector that majorizes X? the meaning of majorization can be found here: https://en.wikipedia.org/wiki/Majorization. Certainly, $(n , 0 , \ldots , 0)$ is an answer, but I want a nontrivial vector. In particular,I'm looking for some nontrivial known results . Thanks.

Lattices that top is the top of its join-irreducibles, such that a random element is almost surely greater then any given join-irreducible

Let $(L,\leq,0,1)$ be a lattice, and let's denote by $JI(L)$ the set of its join-irreducibles (i.e. elements that are not the lowest grater bound of two other elements). We suppose that $\sup JI(L)=1$. and that $\mathbb P$ is a probability on L such that ideals and filters are measurable and singleton have probability 0. Let's call such a lattice a "reach-irreducible lattice" (RIB). If the cardinality of L is that of the continuum" we can say "continuum reach-irreducible lattice" (CRIL) Does there exist in any L that is a continuum-reach-irreducible lattice, $g\in JI(L)$ such that $\mathbb P(\left\{x\in L,\, g\leq x\right\})<1$. Related discussions on the MSE are https://math.stackexchange.com/questions/2737618/lattice-generated-by-join-irreducible-elements-such-that-any-principal-filter-c and https://math.stackexchange.com/questions/2742357/probability-martin-axiom-and-the-weak-frankl-conjecture The first link is an imperfect attempt to fit with the motivation of this question, that is explained in the second link. If the answer to this question is yes, then a weak version of the Frankl Conjecture ("WFC")- that is also an open problem - is true (see MSE links). Note that in both links, the lattices that I built assuming that WFC is wrong are not exactly CRIL, but up to small details, one can easily get CRIL from them. Note also that the cardinality condition is just given to fit with WFC, but it would be nice indeed if the answer of the question is yes for any RIL. And if it is not, it might also give some useful informations, so I would also be happy to read answers and comments about general RIL.

PhD dissertations that solve an established open problem

I search for a big list of open problems which have been solved in a PhD thesis by the Author of the thesis (or with collaboration of her/his supervisor). In my question I search for every possible open problem but I prefer (but not limited) to receive answers about those open problems which had been unsolved for at least (about) 25 years and before the appearance of the ultimate solution, there had been significant attentions and efforts for solving it. I mean that the problem was not a forgotten problem. If the Gauss proof of the fundamental theorem of algebra did not had a gap, then his proof could be an important example of such dissertations. I ask the moderators to consider this question as a wiki question.

Status of two Banach space theory open problems posted by Pełczyński

In the book 'Open Problems in the Geometry and Analysis of Banach Spaces', I am interested in the following two problems. Problem 1: Let X be a separable infinite-dimensional Banach space that is not isomorphic to a Hilbert space. (i) (A. Pełczyński) Does there exist an infinite dimensional subspace of X with Schauder basis that is not complemented in $X?$ (ii) (A. Pełczyński) Do there exist two infinite-dimensional subspaces of X with Schauder basis that are not isomorphic? I would like to know status of the two problems above. Are they solved or still open?

Strengthened version of Isoperimetric inequality with n-polygon

Let $ABCD$ be a convex quadrilateral with the lengths a, b, c, d and the area S. The main result in our paper equivalent to: \begin{equation} a^2+b^2+c^2+d^2 \ge 4S + \frac{\sqrt{3}-1}{\sqrt{3}}\sum{(a-b)^2}\end{equation} where $\sum{(a-b)^2}=(a-b)^2+(a-c)^2+(a-d)^2+(b-c)^2+(b-d)^2+(c-d)^2$ and note that $\frac{\sqrt{3}-1}{\sqrt{3}}$ is the best constant for this inequality. Similarly with the same form above apply to n-polygon, I propose a conjecture that: Let a convex polygon $A_1A_2...A_n$ with the lengths are $a_1, a_2, ...a_n$ and area S we have: \begin{equation} \sum_i^n{a_i^2} \ge 4\tan{\frac{\pi}{n}}S + k\sum_{i < j}{(a_i-a_j)^2}\end{equation} I guess that $k=tan{\frac{\pi}{n}}-tan{\frac{\pi}{n+2}}$ I am looking for a proof of the inequality above. Note that using Isoperimetric inequality we can prove that: \begin{equation} \sum_i^n{a_i^2} \ge 4\tan{\frac{\pi}{n}}S\end{equation} Case n=3: Hadwiger-Finsler inequality, $k=1 \approx 1.00550827956352=tan{\frac{\pi}{3}}-tan{\frac{\pi}{5}}$: \begin{equation}a^{2} + b^{2} + c^{2} \geq 4 \sqrt{3}S+ (a - b)^{2} + (b - c)^{2} + (c - a)^{2}\end{equation} Case n=4: our paper, $k=\frac{\sqrt{3}-1}{\sqrt{3}}$, $k=tan{\frac{\pi}{4}}-tan{\frac{\pi}{6}}$ \begin{equation} a^2+b^2+c^2+d^2 \ge 4S + \frac{\sqrt{3}-1}{\sqrt{3}}\sum{(a-b)^2}\end{equation} See also: Weitzenböck's inequality Hadwiger-Finsler inequality Isoperimetric inequality.

Relative to Isoperimetric inequality with n-polygon

Since Brahmagupta's formula and Bretschneider's formula we have the inequality: Any two quardrilaterals $A_1A_2A_3A_4$ and $B_1B_2B_3B_4$ with the same sidelengths and $A_1A_2A_3A_4$ is a cyclic but $B_1B_2B_3B_4$ is not a cyclic then area of $A_1A_2A_3A_4$ $\ge$ area of $B_1B_2B_3B_4$ Isoperimetric inequality state that: For the length L of a closed curve and the area A of the planar region that it encloses, that $L^2 \ge 4\pi .Area$ and that equality holds if and only if the curve is a circle. I conjecture that: Let $A_1A_2...A_n$ and $B_1B_2...B_n$ be two n-polygons with the lengths $a_1, a_2,...,a_n$ and $b_1, b_2,...,b_n$ such that with $i \in n$ then exist $j \in n$ such that $a_i=b_j$. If $A_1A_2...A_n$ is a cyclic and $B_1B_2...B_n$ is not a cyclic then area of $A_1A_2...A_n$ $\ge$ area of $B_1B_2...B_n$. I am looking for the proof of the inequality above.

V3-018185 | MO-300505

Status of an open problem in isometric aspect of Banach space theory

The following open problem is taken from the book Open Problems in the Geometry and Analysis of Banach Spaces, page $40.$ Problem $84:$ Assume that X is an infinite-dimensional separable Banach space such that for any pair of points x and y in the unit sphere of X there exists a linear isometry from X onto X such that $Tx=y.$ Is X linearly isometric to a Hilbert space? After stating the problem, authors mentioned that the problem holds true for finite-dimensional spaces but not for non separable spaces. Then they point to the reference,page 255 which contains the problem above. My question: Does anyone know whether the problem is still open?If yes, what is a good reference? The authors of the book mentioned that problem 84 is an old classical open problem. So I suspect that there should be some papers available on solving the problem partially or fully.

Density of the Klarner-Rado Sequence

Consider the Klarner-Rado sequence OEIS A005658 defined by the rule: the sequence starts with 1, and if it contains n it also contains $2n$, $3n+2$ and $6n+3$. According to R. Guy's popular article, Klarner conjectures that this set has positive density. Lagarias in The Ultimate Challenge book says the conjecture is open. Question: should we believe or disbelieve the conjecture? Is there a heuristic argument explaining what's going on here?

Upper bound of the expectation of sum of the absolute value pairs

We have two arrays A,B of length n. All values are i.i.d drawn from same distribution on $[0,1]$. If we sort A,B in non-decreasing order and let $A_{(i)},B_{(i)}$ denote the i-th value in the sorted array. Then we have $S=\sum_{i=1}^n|A_{(i)}-B_{(i)}|$. What is the upper bound of $\mathbb{E}[S]$? I believe it must be the uniform distribution in order to get the upper bound, but I can't prove that. I've searched order statistics and I think that may give me some upper bound, but the expression is too complex and I can't complete the derivation.

Algebraic version of unilateral shift

It was confirmed that Wold-type decomposition can be extended from von Neumann algebras to Baer*-rings (see this paper). By algebraic tools the notion of unilateral shifts is successfully transmitted to Baer*-rings (see Def. 2.3 of the paper). I have a question in this context. To state it, some notations are given from the paper. $\bullet$ For a given y in A, the left projection of y is the smallest projection $[y]$ satisfying in $[y]y=y$. When A is a von algebra contained in $B(H)$ for some Hilbert space H then, $[y]$ is just the range projection of the operator y. $\bullet$ Let x be an isometry element in A that is $x^*x=1$. A projection p is called wandering for x if $[x^np][x^mq]=0$ for every different pair of natural numbers m and n. $\bullet$ An isometry x is called a unilateral shift in A if there exists a wandering projection p with $\sup_{n\geq0} \sum_0^n[x^np]=1$. Wold-decomposition in Baer*-rings. Let x be an isometry in A. There exists a commuting projection q with x such that x is decomposed to a direct sum $x=xq+(1-q)x$ of a unitary xq and unilateral shift $(1-q)x$ in the corner sub-rings Aq and $A(1-q)$ respectively. Question. Let A be a Baer*-ring. Let x be a unilateral shift and q be a finite projection in A. Can we conclude that $\inf_{n\geq1}[x^{*n}q]=0$? The answer is clearly yes in von Neumann algebras and seems to be YES in general case.

A question related to Conways 99 graph problem

I have observed that the number of triangles $\frac{vk}{6}$ of a strongly regular graph with parameters $(v,k,1,2)$ is given by the coefficient $2(k-1)$ in the molien series of the "4-D extraspecial group $2^{1+2\cdot 2}$": For example the beginning of the molien series is: $1 + t^2 + 5t^4 + 6t^6 + 15t^8 + 19t^{10} + 35t^{12} + 44t^{14} + 69t^{16} + 85t^{18}\\ + 121t^{20} + 146t^{22} + 195t^{24} + 231t^{26} + 295t^{28} + 344t^{30} + 425t^{32} + O(t^{34})$ We know that for $srg(9,4,1,2)$ we have $\frac{9\cdot4}{6}=6$ triangles and the coeffient $6 \cdot t^6$ tells us that at $6 = 2\cdot(4-1)$ we have 6 triangles. We know that for $srg(99,14,1,2)$ we have $\frac{99\cdot14}{6}=231$ triangles and the coeffient $231 \cdot t^{26}$ tells us that at $26 = 2\cdot(14-1)$ we have 231 triangles. And so on ... I have checked this for all known parameters for such hypothetical graphs: The parameters of all such graphs are: $(9,4,1,2),(99,14,1,2),(243,22,1,2),(6273,112,1,2),(494019,994,1,2)$ of which only the $n=9$ and $n=243$ are known. The Conway 99-graph problem asks if there exists such graph with 99 vertices. The number of triangles in such a (hypthetical) graph is: $6,231,891,117096,81842481$ (1) My (naive) question is, if there is a (deeper) connection, and maybe one can find unified way to construct all such graphs using the group above and the invariant homogenous polynomials (if this is not too much to ask)? (2) The 6 homogenous invariants of degree 6 are: $\frac14x_0^2x_1^2x_2^2 + \frac14x_0^2x_1^2x_3^2 + \frac14x_0^2x_2^2x_3^2 + \frac14x_1^2x_2^2x_3^2,$ $ \frac14x_0^4x_2^2 + \frac14x_0^2x_2^4 + \frac14x_1^4x_3^2 + \frac14x_1^2x_3^4,$ $ \frac14x_0^6 + \frac14x_1^6 + \frac14x_2^6 + \frac14x_3^6,$ $ \frac14x_0^3x_1x_2x_3 + \frac14x_0x_1^3x_2x_3 + \frac14x_0x_1x_2^3x_3 + \frac14x_0x_1x_2x_3^3,$ $\frac14x_1^4x_2^2 + \frac14x_1^2x_2^4 + \frac14x_0^4x_3^2 + \frac14x_0^2x_3^4,$ $ \frac14x_0^4x_1^2 + \frac14x_0^2x_1^4 + \frac14x_2^4x_3^2 + \frac14x_2^2x_3^4$ My question is, if one can find a way to associate to each such a homogenous invariant a unique triangle. I am struggling to find out what the set of vertices V with $|V|=9$ is. Edit: I found some way for the case $\deg=6$ with a brute force attack in SAGEMATH. But this attack doesn't work for $\deg=26$ since there I have to compute the common zeros of the 231 homogenous polynomials over some finite field. The problem I am facing is that the ideal generated by the homogenous invariants has dimension 2. But for a finite field there should be at most finitely many zeros. Any idea how to solve this in SAGEMATH (Computing the common zeros over some finite field?) J is the ideal of interest: sage: [I.gens() for I in J.minimal_associated_primes()] [[x1 + x2, x0 + x3], [x2 + x3, x0 + x1], [x1 + x3, x0 + x2]] sage: J.dimension() 2 https://oeis.org/A030533 https://pure.tue.nl/ws/portalfiles/portal/2157517 https://people.maths.bris.ac.uk/~matyd/GroupNames/1/ES+(2,2).html

$\sum_{i<j} x_{ij}^\alpha \ge \sum_{i<j} y_{ij}^\alpha $ for arbitrary cyclic polygons

I am looking for a proof of the inequality as follows: Conjecture: Let $A_1A_2....A_n$ be the regular polygon inscribed in a circle (O). Let $B_1B_2....B_n$ be another polygon inscribed in the circle (O). Denote $x_{ij}=A_iA_j$ and $y_{ij}=B_{i}B_{j}$ then: $$\sum_{i<j} x_{ij}^\alpha \ge \sum_{i<j} y_{ij}^\alpha $$ Where $ 1 \leq \alpha \leq 2$. The case $ \alpha = 1 $ was proved in our paper in here The case $ \alpha = 2 $ was proved in here Example: $n=3$, let ABC be a triangle with sidelength a, b, c then we have the inequality as follows: $$a^\alpha + b^\alpha+ c^\alpha \leq 3\times 3^{\frac{\alpha}{2}}R^\alpha$$ Where $ 1 \leq \alpha \leq 2$ and R is circumradius. See also:

A symmetric polynomial inequality

I improve my previous question. Because this conjecture is exactly natural development of A Muirhead Like Inequality and Muirhead's Inequality so I think the conjecture is true. But I can not prove it. So I am looking for a proof of a conjecture as follows. Inequality 1: Let $n>2$ and $1 \le m \le n$ be integers. Let $x_1, \dots, x_n$ and $y_1,\dots, y_n$ be nonnegative real numbers such that $(x_1,\dots, x_n)$ majorizes $(y_1,\dots, y_n)$. Then for all reals $0 \leq a_1, a_2,\cdots,a_n \leq 1$, $$\sum\limits_{sym}\left(\sum\limits_{sym} x_{i_1}^{a_{p_1}} \cdots x_{i_m}^{a_{p_m}} \right) \leq \sum\limits_{sym}\left(\sum\limits_{sym} y_{i_1}^{a_{p_1}} \cdots y_{i_m}^{a_{p_m}} \right) $$ The summations are of course meant to be respectively over all m-tuples $(i_1,\dots,i_m),(p_1,\dots,p_m)$ with pairwise distinct entries. When $m=n$ this inequality is A Muirhead Like Inequality Inequality 2: Let $n>2$ and $1 \le m \le n$ be integers. Let $x_1, \dots, x_n$ and $y_1,\dots, y_n$ be nonnegative real numbers such that $(x_1,\dots, x_n)$ majorizes $(y_1,\dots, y_n)$. Then for all reals $ a_1, a_2,\dots,a_n \geq 0$, $$\sum\limits_{sym}\left(\sum\limits_{sym} a_{i_1}^{x_{p_1}} \cdots a_{i_m}^{x_{p_m}} \right) \geq \sum\limits_{sym}\left(\sum\limits_{sym} a_{i_1}^{y_{p_1}} \cdots a_{i_m}^{y_{p_m}} \right)$$ When $m=n$, this inequality is just Muirhead.

A rearrangement inequality for exponentiation function

Update: A year ago, but the first answer is not clear with me. I bounty this question again. My question: I am looking for a proof or counterexample to the following inequality: If $n \in \mathbb{N}$, and $a_1 \ge a_2 \ge \cdots \ge a_n \ge 0$ and $\alpha_1 \ge \alpha_2 \ge \cdots \ge \alpha_n \ge 0$ then $${\left(\sum_{i=1}^{n}{a_i^{\alpha_i}} \right)}^n \ge \prod_{i=1}^{n}{\left(\sum_{j=1}^{n}{a_i^{\alpha_j}} \right)}$$ If $n \in \mathbb{N}$ and $a_1 \ge a_2 \ge \cdots \ge a_n \ge 0$ and $0 \le \alpha_1 \le \alpha_2 \le \cdots \le \alpha_n$ then $${\left(\sum_{i=1}^{n}{a_i^{\alpha_i}} \right)}^n \le \prod_{i=1}^{n}{\left(\sum_{j=1}^{n}{a_i^{\alpha_j}} \right)}$$ Moreover equality holds in either case if and only if $a_1=a_2=a_3=...=a_n$. [The original question claimed a proof when $n=2$ or $n=3$.]

Existence of a Lipschitz map from a positive measure set to a ball

Question. If $A\subset \mathbb{R}^n$ is any set of positive Lebesgue n-measure, does there exists a Lipschitz map $f:A\to\mathbb{R}^n$ such that $f(A)$ is a ball with the same measure? In dimension $n=1$, such a map is easily found by defining $f(x) = \mathcal{L}^1(A\cap [0,x])$. In higher dimensions the problem becomes much more difficult. There is a short discussion on the topic in Ch. 7.10 of Mattila's 1995 book Geometry of Sets and Measures in Euclidean Spaces, where it is said that "Recently Preiss [6] proved that if A is an $\mathcal{L}^2$ measurable subset of $\mathbb{R}^2$ with $\mathcal{L}^2(A) > 0$, there is a Lipschitz map $f:A\to \mathbb{R}^2$ such that fA is a disc. In $\mathbb{R}^n$ for $n\geq 3$ the problem is unsolved." The reference given is [6] D. Preiss. Lipschitzian images of planar sets of positive measure, preprint However I was unable to find the mentioned paper of Preiss anywhere. At least no paper with such a title seems to exist on MathSciNet, arXiv or Preiss's list of publications. Given that Mattila referred to the result as "recent" in 1995, it seems unlikely that the paper would still be a preprint, so a few possibilities come to mind: The title changed before publication An error in the proof was found and the paper was never published The result was included in a different paper Any information about what has happened to the paper of Preiss, or any other references or information about the current state of the problem would be much appreciated.

Smallest dilation of a quadrilateral?

What is the smallest dilation of a quadrilateral in $\mathbb{R}^d$? This may be an open problem; my question is: Is this indeed open? It will take me some time to explain the terms. The notion of dilation derives from Gromov, as far as I know (He defines a version in Metric Structures for Riemannian and Non-Riemannian Spaces, p.11, although he called it distortion). I came upon it myself via t-spanners. The version in which I am interested is this. Let P be a polygon (its boundary, not its interior), and x,y two points on P. You can think of P in $\mathbb{R}^2$, but also $\mathbb{R}^3$ and $\mathbb{R}^d$ for $d>3$ are interesting. Define $\delta(x,y)$ as the maximum (supremum) of $d_P(x,y) / | x y |$, where $d_P(x,y)$ is the distance between x and y following P (the shortest path staying on the closed path that consitutes P), and $|xy|$ is the Euclidean distance in $\mathbb{R}^d$. Thus $\delta(x,y)$ measures how much P dilates w.r.t. Euclidean distance. I am interested in the minimum value $\delta(P)$ of $\delta(x,y)$ over all $x,y \in P$, for all n-gons P, for fixed n. Example 1. If P is a unit square, then $\delta(x,y)$ for x,y opposite corners is $\sqrt{2}$, but $\delta(P)=2$ because with x,y midpoints of opposite sides, $\delta(x,y)= 2/1$. Example 2. If P is an equilateral triangle, $\delta(P)=2$, as shown in the figure. In fact, the dilation of any triangle is ≥ 2 [Lemma 7 in the 2nd paper below]. Example 3. It is known the the dilation of any closed curve C satisfies $\delta(C) \ge \pi/2$, with equality achieved only by the circle. [Corollary 23 in the first paper below.] This is (apparently) due to Gromov. So I finally come to my question. By reading these two papers, "Geometric Dilation of Closed Planar Curves: New Lower Bounds," and "On Geometric Dilation and Halving Chords," it appears to me that the minimum dilation of a quadrilateral in $\mathbb{R}^2$ (and $\mathbb{R}^d$) is not known. I had heard this was the case three years ago in a seminar in Brussels, but (a) I didn't quite believe it, (b) it was hearsay, and (c) it is now out of date. I am trying to clarify with the authors of these papers, but in parallel I would appreciate any information on the status of this question. The latter paper cited above proves a lower bound of $4 \tan(\pi/8) \approx 1.66$ (if I have interpreted it correctly). Addendum. I don't want to close-out this question, but I have heard from one of the authors of the above cited papers, and indeed it appears that the dilation of a planar quadrilateral is unknown [as of July 2010, the original posting date]. So I have tentatively tagged this as an open-problem, and I will update if new information surfaces. Thanks for everyone's interest and input!

Is Lebesgue's "universal covering" problem still open?

The following problem has been attributed to Lebesgue. Let "set" denote any subset of the Euclidean plane. What is the greatest lower bound of the diameter of any set which contains a subset congruent to every set of diameter 1? There are a number of interesting geometric problems of this type. Is it possible that some of them may be difficult to solve because the solution is a real irrational number which (when expressed in decimal form) is not even recursive-and so cannot be approximated in the usual way?

Integral equality of 1st intrinsic volume of spheroid

Computations suggest that $$\int_{0}^{\infty}\int_{0}^{\infty} \sqrt{x+y^2} \cdot e^{-\frac{1}{2}(\frac{x}{s}+s^2y^2)}dxdy=\frac{2}{s}+\frac{2s^2\arctan(\sqrt{s^3-1})}{\sqrt{s^3-1}}.$$ The question is how to prove this equality. Background: this is the mean width of an ellipsoid with semiaxes $s,s,1/s^2$ and this almost completes the proof of the uniqueness hypothesis of an ellipsoid with given intrinsic volumes.

Zero divisors in complex group algebras of residually finite groups

Conjecture. There exists a function $f:\mathbb{N} \rightarrow \mathbb{N}$ such that if α and β are non-zero elements of the complex group algebra $\mathbb{C}[G]$ of a finite group G such that $1\in \text{supp}(\alpha) \cap \text{supp}(\beta)$, $|\text{supp}(\alpha)|\leq |\text{supp}(\beta)|$ and $\alpha \cdot \beta =0$, then $\text{exp}\big (\langle \text{supp}(\alpha) \rangle \big) \leq f(|\text{supp}(\beta)|)$, where $\text{exp}(H)$ denotes the exponent of a finite group H and $\text{supp}(\gamma)$ for

an element $\gamma=\sum_{g\in G} \gamma_g \; g \in \mathbb{C}[G]$ denotes the set $\{ g\in G \;|\; \gamma_g \not=0\}$. Motivation. If the conjecture is true, then the support of any zero divisor of the complex group algebra of any residually finite group generates a finite subgroup. Proof. Let α be a non-zero element of $\mathbb{C}[G]$ for some residually finite group G such that $\alpha \cdot \beta =0$ for some non-zero $\beta \in \mathbb{C}[G]$. Let $H=\langle \text{supp}(\alpha) \rangle$. By Zelmanov's celebrated result on restricted Burnside problem, it is enough to show that the exponent of H is finite. Since H is finitely generated residually finite, there exists a descending series $H=N_1\geq N_2 \geq \cdots$ of normal subgroups H of finite index such that $\cap_{i\in\mathbb{N}} N_i=1$. Note that there exists $k\in\mathbb{N}$ such that $\bar{\alpha} \cdot \bar{\beta}=0$ in $\mathbb{C}[H/N_i]$ for all $i\geq k$ and $|\text{supp}(\bar{\beta})|=|\text{supp}(\beta)|=:t$, where $\bar{}$ is the natural ring epimorphism from $\mathbb{C}[H]$ onto $\mathbb{C}[H/N_i]$. Now if the above conjecture is true then $\text{exp}(H/N_i)\leq f(t)$ and so $\text{exp}(H)$ is finite. This completes the proof. If the above proof and conjecture are true then the complex group algebras of torsion-free residually finite groups have no zero divisor.

Zero divisors with support size 3 in complex group algebras of residually finite groups

Conjecture. There exists a function $f:\mathbb{N} \rightarrow \mathbb{N}$ such that if β is a non-zero element of the complex group algebra $\mathbb{C}[G]$ of a finite group G such that $1\in \text{supp}(\beta)$, and $(1+x+y) \cdot \beta =0$ or $(1+x-y) \cdot \beta =0$ for some distinct and nontrivial $x,y\in G$, then $\text{exp}\big (\langle x,y \rangle \big) \leq f(|\text{supp}(\beta)|)$, where $\text{exp}(H)$ denotes the exponent of a finite group H and $\text{supp}(\gamma)$ for an element $\gamma=\sum_{g\in G} \gamma_g \; g \in \mathbb{C}[G]$ denotes the set $\{ g\in G \;|\; \gamma_g \not=0\}$. Motivation. If the conjecture is true, then the support of any zero divisor of the form $1+x+y$ or $1+x-y$ of the complex group algebra of any residually finite group generates a finite subgroup. Proof. Let $\alpha=1+x+y$ or $1+x-y$ be a non-zero element of $\mathbb{C}[G]$ for some residually finite group G such that $\alpha \cdot \beta =0$ for some non-zero $\beta \in \mathbb{C}[G]$. Let $H=\langle \text{supp}(\alpha) \rangle$. By Zelmanov's celebrated result on restricted Burnside problem, it is enough to show that the exponent of H is finite. Since H is finitely generated residually finite, there exists a descending series $H=N_1\geq N_2 \geq \cdots$ of normal subgroups H of finite index such that $\cap_{i\in\mathbb{N}} N_i=1$. Note that there exists $k\in\mathbb{N}$ such that $\bar{\alpha} \cdot \bar{\beta}=0$ in $\mathbb{C}[H/N_i]$ for all $i\geq k$ and $|\text{supp}(\bar{\beta})|=|\text{supp}(\beta)|=:t$, where $\bar{}$ is the natural ring epimorphism from $\mathbb{C}[H]$ onto $\mathbb{C}[H/N_i]$. Now if the above conjecture is true then $\text{exp}(H/N_i)\leq f(t)$ and so $\text{exp}(H)$ is finite. This completes the proof. If the above proof and conjecture are true then the integral group algebras of torsion-free residually finite groups have no zero divisor with support size 3.

Asymptotics of Littlewood polynomials

Littlewood in [L] states several conjectures regarding asymptotics of polynomials with ±1 coefficients. He considers the class $\mathscr F$ of polynomials of form $\sum^n\pm z^m$ and asks whether there exists a sequence f_n in $\mathscr F$ such that $$A\leq\frac{|f_n(\theta)|}{\sqrt{n+1}}\leq B$$ for large n's. 1. I'd like to know if this is still open and would be grateful if someone could provide references for recent survey papers. 2. If the conjecture is not settled yet, I was thinking if one can apply integer programming methods to tackle the problem? Update 1 As pointed out by Fedor, J-P. Kahane's work gives an elegant proof for polynomials with unimodular coefficients. His result is as follows(I didn't translate it to English as seems rather easy to understand): Theoreme. Il existe une suite de polynomes $$P_n(z)=\sum_{m=1}^{n}a_{m,n}z^m,\,(|a_{m,n}| = 1; \, n=1,2,\ldots,m=1,\ldots,n)$$ et une suite ϵ_n positive tendant vers 0 telles que pour tout z de module 1 on ait$$(1-\epsilon_n)\sqrt{n}\leq|P_n(z)|\leq(1+\epsilon_n)\sqrt{n}.$$ Numerical experiments suggest there might be hope to construct a sequence of $P_n\in\mathbb {Z}_2[x]$ which satisfies Kahane's asymptotics. [L]Littlewood, J. E., On polynomials $\sum^n\pm z^m, \sum^n e^{\alpha_mi}z^m, z = e^{\theta i}$, J. Lond. Math. Soc. 41, 367-376 (1966). ZBL0142.32603.

The "sensitivity" of 2-colorings of the d-dimensional integer lattice

Consider the d-dimensional integer lattice, Z^d. Call two points in Z^d "neighbors" if their Euclidean distance is 1 (i.e., if they differ by 1 on exactly one coordinate). Let C be a two-coloring of Z^d, which makes each point either red or blue. We'll assume C has the following "nontriviality" property: the origin is colored red, but on each of the d axes through the origin, there's a point on that axis that's colored blue. Let the "sensitivity" of a point x with respect to C, or $s_x(C)$, be the number of x's neighbors that are colored differently from x. Then let $s(C) = \max_{x \in Z^d} s_x(C)$. QUESTION: Can you give me any decent lower bound on $s(C)$ in terms of d? For example, that $s(C) \ge k \sqrt{d}$ for some constant $k > 0$? REMARK 1: If you prove a lower bound of the form $k d^l$ (for

constants $k,l > 0$), then you'll have solved an old open problem in the study of Boolean functions, namely the "sensitivity versus block sensitivity" problem (posed by Noam Nisan in 1991). But please don't let that discourage you! My variant feels more approachable, and maybe something is even already known about it. (I'll be happy to supply full details of the reduction on request. But here's the basic idea: let $f : \lbrace 0,1 \rbrace ^n \rightarrow \lbrace 0,1 \rbrace$ be a Boolean function such that the block sensitivity $bs(f)$ is much much larger than the sensitivity $s(f)$. Then there must be an input x of f that has $bs(f)$ disjoint sensitive blocks. Let $d=bs(f)$. Then we can construct a two-coloring of Z^d with the properties listed above, and such that $s(C) \le 2 s(f)$ where $s(f)$ is the sensitivity of f. The input x gets mapped to the origin of Z^d, while each of the d sensitive blocks of x gets mapped to one of the axes of Z^d. To map a Boolean assignment to an integer, in a way that preserves the sensitivity, we use the Gray Code. Finally, we color each point $y \in Z^d$ either red or blue, depending on whether $f(x)$ is 0 or 1 for the corresponding Boolean point x.) REMARK 2: I can give an example of a coloring with $s(C) = O(\sqrt{d})$, meaning that $s(C) \ge k \sqrt{d}$ really is the best lower bound one can hope for. This coloring can be obtained by starting from "Rubinstein's function" -- a Boolean function $f : \lbrace 0,1 \rbrace ^n \rightarrow \lbrace 0,1 \rbrace$ with $bs(f) = n/2$ and $s(f) = 2 \sqrt{n}$ -- and then applying the reduction sketched in Remark 1. (For those who are interested, let me now go ahead and describe a coloring with $s(C) = O(\sqrt{d})$ explicitly. Assume for simplicity that d is a perfect square. Partition the d coordinates of x into $\sqrt{d}$ "blocks" of $\sqrt{d}$ coordinates each. Then we'll color x blue, if and only if at least one of the blocks has a single coordinate equal to 2 and all other coordinates equal to 0. I'll leave it as an exercise for you to verify that $s(C) = 2 \sqrt{d}$.) Note: I edited the above paragraph a little, to simplify the construction and insert a missing factor of 2. REMARK 3: At the moment, I don't even have a proof that $s(C)$ has to grow with d (!!). But I suspect at least $s(C) \ge k \log d$ ought to be doable. EDIT: Sorry to switch notations in the middle of the game, but I have a better one if you want to talk about low dimensions (per domotorp's question below)! Let's let $r_x(C)$ be the number of axes (up/down, left/right, etc.) along which x has a neighbor that's colored differently than x is. Then let $r(C) = \max_x r_x(C)$. Clearly $r(C) \le s(C) \le 2r(C)$ for all C. In fact, something even stronger than that is true: given any coloring C, one can create a new coloring C' that satisfies $s(C')=r(C)$, by simply "blowing up" each point x into a cube of 2^d points, which are all colored the same way x was colored in C. The nontriviality and sensitivity properties will clearly be preserved; all this transformation does is to eliminate the problem of a point having two differently-colored neighbors along the same axis. So without loss of generality, we can shift attention to $r(C)$. Now let $r_d = \min_C r(C)$ over all nontrivial colorings C of Z^d. Then here's what I know: $r_1 = 1$ $r_2 = 2$ $r_3 = 2$ $r_4 = 2$ $r_5 \in \lbrace 2,3 \rbrace$ UPDATE: I created an image that shows an explicit coloring of Z^3 that satisfies both the nontriviality condition and $r(C)=2$. (That is, from every point, you can change color by moving along at most 2 different axes.) As explained above, this can easily be converted into a coloring with $s(C)=2$ as well. (source) domotorp is right that proving $r_5=3$ could be a great start...

Is it known how the Sigma Algebra generated by Jordan measurable sets compares to universally measurable sets and analytic sets?

Unlike the collection L of Lebesgue measurable sets, the collection J of Jordan measurable sets do not form a Sigma algebra. (A set is Jordan measurable if and only if its characteristic function is Riemann integrable, and the characteristic function of a singleton is Riemann integrable, but the characteristic function of the rational numbers is not.) But we can still talk about $\sigma(J)$, the Sigma algebra generated by J. Now in this 1993 journal paper, K.G. Johnson shows that the Borel Sigma algebra is a proper subset of $\sigma(J)$ which is a proper subset of the Lebesgue Sigma algebra, and that a set is in $\sigma(J)$ if and only if it can be written as a union of a Borel set and a subset of a measure 0 F_σ set. But Johnsons says there are two questions he doesn’t know the answer to: Where does $\sigma(J)$ stand relative to the analytic sets ... and relative to the universally measurable sets[?] My question is, have either of these questions been answered in the two decades since this paper was published? Is it known whether there are analytic sets which are not in $\sigma(J)$ or vice versa? Is it known whether there are universally measurable sets which are not in $\sigma(J)$ or vice versa? Or are these still open problems?

For what sets does the Lebesgue Differentiation Theorem hold in one dimension?

Lebesgue's differentiation theorem states that if x is a point in $\mathbb{R}^n$ and $f:\mathbb{R}^n\rightarrow\mathbb{R}$ is a Lebesgue integrable function, then the limit of $\frac{\int_B f d\lambda}{\lambda(B)}$ over all balls B centered at x as the diameter of B goes to 0 is equal almost everywhere to $f(x)$. But if you replace balls with other kinds of set with diameter going to 0, this need not be true. For instance it need not be true if you replace balls with rectangles. But my question is, what is known about what collections of sets the Lebesgue Differentiation Theorem holds for in one dimension? We know it holds for bounded intervals. Does it hold for finite unions of bounded open intervals? What about bounded Borel sets? What about bounded Lebesgue measurable sets in general? Or are all these open problems?

V3-018207 | MO-316075

Is a maximal set of rectangles known for which Lebesgue’s Differentiation Theorem holds true?

Lebesgue's differentiation theorem states that if x is a point in $\mathbb{R}^n$ and $f:\mathbb{R}^n\rightarrow\mathbb{R}$ is a Lebesgue integrable function, then the limit of $\frac{\int_B f d\lambda}{\lambda(B)}$ over all balls B centered at x as the diameter of B goes to 0 is equal almost everywhere to $f(x)$. But if you replace balls with other kinds of set with diameter going to 0, this need not be true. For instance it need not be

true if you replace balls with rectangles, even rectangles with sides are parallel to the coordinate axes. But if we restrict things to L^p functions where $1<p<\infty$, then Lebesgue's differentiation theorem does hold true for rectangles with sides parallel to the coordinate axes, but it does not hold true for arbitrary rectangles. So my question is, is a maximal set of directions known for which Lebesgue's differentiation theorem holds for L^p functions for the collection of all rectangles oriented in those directions? Now this journal paper says that a maximal set of directions is not known for tubes in $\mathbb{R}^n$ for which Lebesgue's differentiation theorem holds (though the paper makes a conjecture about it). And a rectangle is nothing but a tube in $\mathbb{R}^2$. But it's possible that the answer is known for this special case.

An open problem in Sobolev spaces

Let $\Omega\subset\mathbb{R}^n$ be a bounded domain. Suppose that there there is a bounded extension operator $$ E:W^{1,p}(\Omega)\to W^{1,p}(\mathbb{R}^n) \quad \text{and} \quad E:W^{1,q}(\Omega)\to W^{1,q}(\mathbb{R}^n), $$ where $1\leq p<q\leq\infty$ (or $1<p<q<\infty$ if you find it easier). Open problem. Does it follow that $$ E:W^{1,r}(\Omega)\to W^{1,r}(\mathbb{R}^n) $$ for all $p<r<q$? Some partial results are known, but the general case seems to be difficult. It looks like a simple interpolation exercise, but it is not. Later, when I have time I will add some references to known results.

A tantalizing Gamma quotient to challenge the Rohrlich-Lang Conjecture

The Rohrlich-Lang Conjecture for polynomial relations in Gamma values predicts that all polynomial relations between Gamma values over $\mathbb Q$ come from the functional equations satisfied by the Gamma function. An other statement, somewhat narrower: if a quotient of products of gamma values over $\mathbb Q$ is an algebraic number, then it can be evaluated by using only the well-known reflection and multiplication formulae. Lang, S. - Relations de distributions et exemples classiques. Séminaire Delange-Pisot-Poitou, 19e année: 1977/78, Théorie des nombres, Fasc. 2, Exp. N° 40, 6 p. Collected Papers, vol. III, Springer (2000), 59-65. I am wondering what that means for the following. Define $$A:=\prod_{k=0}^5{\Gamma(\frac{49^k \pmod {78}}{78})}= {\Gamma(\frac{1}{78})\Gamma(\frac{25}{78})\Gamma(\frac{43}{78})\Gamma(\frac{49}{78})\Gamma(\frac{55}{78})\Gamma(\frac{61}{78})} $$ and $$B:=\prod_{k=0}^5 {\Gamma(\frac{7\cdot49^k\pmod {78}}{78})}= \Gamma(\frac{7}{78})\Gamma(\frac{19}{78})\Gamma(\frac{31}{78})\Gamma(\frac{37}{78})\Gamma(\frac{67}{78})\Gamma(\frac{73}{78}).$$ Then numerically, it appears that $$\frac AB=4.$$ Equivalently, as $AB=(2\pi)^6\;\sqrt[3\ \ ]{13}$ by the multiplication formula, we'd have to show $$A=16\pi^3\;\sqrt[6\ \ ]{13}\ \ \text{ and / or }\ \ B=4\pi^3\;\sqrt[6\ \ ]{13}.$$ So the product of the 12 Gamma terms $\Gamma(\frac{6j+1}{78})$ with $j=0,1,3,...,12$ (excluding $j=2$ where $\frac{13}{78}=\frac16$) splits into two halves, one 4 times as big as the other. How to "get rid of" the numerators, which are all $\equiv1\pmod6$? Applying the multiplication formula with step $\frac16$ to each term as suggested in this comment has the same effect (in terms of producing algebraic factors that can then be "ignored") as applying the reflection formula to each term: applying it for instance to A will leave us with $\Gamma(\frac{77}{78})\Gamma(\frac{53}{78})\Gamma(\frac{35}{78})\Gamma(\frac{29}{78})\Gamma(\frac{23}{78})\Gamma(\frac{17}{78})$ in the denominator, no gain. I am aware that there can be surprises like the fact that $\frac{ \Gamma\left(\frac{11}{42}\right)\Gamma\left(\frac{12}{42}\right)}{\Gamma\left(\frac{21}{42}\right)\Gamma\left(\frac2{42}\right)} $ and $\frac{ \Gamma\left(\frac{18}{42}\right)\Gamma\left(\frac{4}{42}\right)}{\Gamma\left(\frac{21}{42}\right)\Gamma\left(\frac1{42}\right)} $ are algebraic and I would not dare to claim that the identity $\frac AB=4$ provides a counterexample to the Rohrlich-Lang conjecture. It is just that the simplicity of the result, being an integer, is particularly intriguing. Is there any other way to evaluate this, using only the functional equations of the Gamma function? Has anybody ever written a program for that (which is rather a combinatorial issue that should not be awfully hard)?

Curves of constant curvature on S^2

Most probably this is a well known question. Consider S^2 with a Riemannian metric. I would like to ask what is known about the structure of the set of simple (without self-intersections) closed curves on it of constant geodesic curvature. Here is a series of questions. 1) Is this true that through each point of S^2 passes a simple closed curve of constant curvature? If not, can one estimate from below the proportion of the area of S^2 covered by such curves? 2) Is it true that for each value of curvature there are at least 2 simple closed curves on S^2 of this curvature? Or maybe even more than 2? 3) What can be said about the global structure of these curves on a generic S^2? Taking the union of all such closed curves we could try to cook up from them a surface (that maps naturally to S^2). Is something known about the topology of this surface? Comments 1) The theorem of Birkhoff states that each Riemannian S^2 contains at least three simple closed geodesics, as Joseph remarks below. 2) For a generic metric on S^2 the set of such curves this set should be one dimensional. Indeed for each fixed value of curvature you can consider

an analogue of the geodesic flow on the space of unite tangent vectors to S^2 and you expect that closed orbits will be isolated. ADDED. Is seems indeed that these are open (and I guess hard) questions. Macbeth gave a very nice reference, that tells in particular that similar questions were raised previously by Arnold, I copy the Macbeth's reference here, so it is visible to everyone: http://count.ucsc.edu/~ginzburg/ARNOLD/mag-post.pdf Update. The following reference : http://arxiv.org/abs/0903.1128 gives a positive answer to question 2) for spheres of non-negative Gaussian curvature provided we consider not only simple curves on S^2 but also curves that bound immersed disks. One more update. There is a new nice article http://arxiv.org/abs/1105.1609 that provides some further results concerning question 2) for S^2 of positive curvature. This article also gives all necessary references from which one can conclude that question 2) was considered by Poincare in 1905, as it is written in the article of S.P. Novikov

Integer valued polynomials over several variables

For simplicity this is about polynomials in just two variables. Any $f\in\mathbb Q[X,Y]$ can be written as a linear combination of monomials X^iY^j and therefore as a sum of polynomials $p_{ij}\in\mathbb Q[X^iY^j]$ over one variable: $$\displaystyle f(X,Y)=p_{00}+\sum_{\gcd(i,j)=1}p_{ij}(X^iY^j).$$ My question: is the subring of all integer valued polynomials f over two variables identical with the subring of all sums of integer valued polynomials p_{ij} over one variable as above? An integer valued polynomial in one variable is a polynomial p with rational coefficients such that $p(\mathbb Z)\subseteq \mathbb Z$. And corresponding for polynomials over several variables. It might be some abuse of language to call p_{ij} polynomials over one variable, they may rather be polynomials over one variable applied to monomials X^iY^j.

Open Problems in Random Graphs

I am a PhD student in mathematics. I'm interested in probabilistic methods in combinatorics and especially random graphs. I am looking for an open problem in this area for my PhD proposal. I know that there are many open problems and conjectures, but I would like to find a "good" problem such that I can get some results during my PhD. It would be very helpful for me if you could suggest a bunch of open problems. Thank you!

Why is $\sup f_- (n) \inf f_+ (m) = \frac{5}{4} $?

This question is an old question from mathstackexchange. Let $f_- (n) = \Pi_{i=0}^n (\sin(i) - \frac{5}{4}) $ And let $ f_+(m) = \Pi_{i=0}^m (\sin(i) + \frac{5}{4}) $ It appears that we have $$\sup f_- (n) \inf f_+ (m) = \frac{5}{4} $$ Why is that so ? Notice $$\int_0^{2 \pi} \ln(\sin(x) + \frac{5}{4}) dx = Re \int_0^{2 \pi} \ln (\sin(x) - \frac{5}{4}) dx = \int_0^{2 \pi} \ln (\cos(x) + \frac{5}{4}) dx = Re \int_0^{2 \pi} \ln(\cos(x) - \frac{5}{4}) dx = 0 $$ $$ \int_0^{2 \pi} \ln (\sin(x) - \frac{5}{4}) dx = \int_0^{2 \pi} \ln (\cos(x) - \frac{5}{4}) dx = 2 \pi^2 i $$ That explains the finite values of $\sup $ and $ \inf $.. well almost. It can be proven that both are finite. But that does not explain the value of their product. Update This is probably not helpful at all , but it can be shown (not easy) that there exist a unique pair of functions $g_-(x) , g_+(x) $, both entire and with period $2 \pi $ such that $$ g_-(n) = f_-(n) , g_+(m) = f_+(m) $$ However i have no closed form for any of those ... As for the numerical test i got about $ln(u) (2 \pi)^{-1}$ correct digits , where $u = m + n$ and the ratio m/n is close to 1. Assuming no round-off errors i ended Up with $1.2499999999(?) $. That was enough to convince me. I often get accused of " no context " or " no effort " but i have NOO idea how to even start here. I considered telescoping but failed and assumed it is not related. Since I also have no closed form for the product I AM STUCK. I get upset when people assume this is homework. It clearly is not imho ! What kind of teacher or book contains this ? --- Example : Taking $m = n = 8000 $ we get $$ max(f_-(1),f_-(2),...,f_-(8000)) = 1,308587092.. $$ $$ min(f_+(1),f_+(2),...,f_+(8000)) = 0,955226916.. $$ $$ 1.308587092.. X 0.955226916.. = 1.249997612208568.. $$ Supporting the claim. I'm not sure if $sup f_+ = 7,93.. $ or the average of $f_+ $ ($ 3,57..$) relate to the above $1,308.. $ and $0,955..$ or the truth of the claimed value $5/4$. In principle we could write the values $1,308..$ and $0,955..$ as complicated integrals. By using the continuum product functions $f_-(v),f_+(w)$ where v,w are positive reals. This is by noticing $ \sum^t \sum_i a_i \exp(t \space i) = \sum_i a_i (\exp((t+1)i) - 1)(\exp(i) - 1)^{-1} $ and noticing the functions f_+,f_- are periodic with 2π. Next with contour integration you can find min and max over that period 2π for the continuum product functions. Then the product of those 2 integrals should give you $\frac{5}{4}$. -- Maybe all of this is unnecessarily complicated and some simple theorems from trigonometry or calculus could easily explain the conjectured value $\frac{5}{4}$ .. but I do not see it. -- -- Update This conjecture is part of a more general phenomenon. For example the second conjecture : Let $g(n) = \prod_{i=0}^n (\sin^2(i) + \frac{9}{16}) $ $$ \sup g(n) \space \inf g(n) = \frac{9}{16} $$ It feels like this second conjecture could somehow follow from the first conjecture since $$-(\cos(n) + \frac{5}{4})(\cos(n) - \frac{5}{4}) = - \cos^2(n) + \frac{25}{16} = \sin^2(n) + \frac{9}{16} $$ And perhaps the first conjecture could also follow from this second one ? Since these are additional questions and I can only accept one answer , I started a new thread with these additional questions :
https://math.stackexchange.com/questions/3000441/why-is-inf-g-sup-g-frac916 ---EDIT--- I want to explain better how to get a closed form for these numbers. I already mentioned that the periods of these functions are 2π and how to use that. But those few lines deserve more attention. Basically this is what we do : We use the fourier series $$ f(x) = \ln(\sin(x) + 5/4) = \sum_{k=1}^{\infty} \frac{-2 \cos(k(x + \pi/2))}{2^k k} $$ Now we use the inverse of the backward difference operator (similar but distinct from the so-called "indefinite sum"

which is defined as inverse of the forward difference operator) In other words we solve for $F(x)$ such that $$F(x) - F(x-1) = f(x)$$ We call this the " continuum sum " (CS) and write/define : $$ CS(f(x),x) := F(x) $$ $$ CS(f(x),y) := F(y) $$ For clarity : $$ \sum_0^y f(x) = CS(f(x),y) - CS(f(x),-1) $$ $$ \sum_0^0 f(x) = CS(f(x),0) - CS(f(x),-1) = f(0) $$ This operator is linear so we make use of that : $$CS(2 \cos(k(x+\pi/2),x) = \csc(k/2) \sin(k(x+1/2 + \pi/2)) -1.$$ This implies that : $$ CS(f(x),x) = F(x) = - \sum_{k=1}^{\infty} \frac{\csc(k/2)\sin(k(x + 1/2 + \pi/2)) - 1}{2^k k} $$ and $$ G(x) = \frac{d F(x)}{dx} = - \sum_{k=1}^{\infty} \frac{\csc(k/2) \cos(k(x+1/2+\pi/2))}{2^k} $$ Now $\sup f_+ = 7.93.. $ is the supremum of $ \exp(F(x) - F(-1) $ and $\inf f_+ = 0.95..$ is the infimum of $ \exp(F(x) - F(-1) $. And both these values are achieved at x such that $G(x) = 0$. The analogue for f_- works. So the numbers from the OP can (more or less) be given by these infinite series and hence the whole conjectures can be stated by these infinite series. We also know for instance $$ \sum_{k=1}^{\infty} \frac{1}{k 2^k} = \ln(2) , \sum_{k=1}^{\infty} \frac{(-1)^k}{k 2^k} = - \ln(3/2) $$ So that is hopefull. Also the max and min of functions can be given by contour integrals but that might not make things easier ? Many trig identities and symmetry are probably related. But I see no clear proof. So that is how we compute the values and it might just help. Also notice : $$ t(x) = \ln(\sin(x) - 5/4) = \ln(-1) + \ln(\sin(-x) + 5/4) = \ln(-1) + \sum_{k=1}^{\infty} \frac{-2 \cos(k(x + \pi/2))}{2^k k} $$ So the other case is no mystery. And ofcourse the case $ \ln(\cos^2(x) - 9/16) $ is also simply related. (trig addition identities can be used) EDIT : I wanted to make as little conjectures as possible when I posted this. Just one question/conjecture per post is the usual rule. But many related conjectures exist. Many might turn out to be equivalent or have already been shown to be equivalent. (such as the analogue cosine cases with $\frac{3}{4}$) I thought it would be best not to flood with related conjectures and post the most important one. Which I did. But one comment of Richard can not be ignored. Richard Stanley wrote $$ \sup f_-(n)^2 - \inf f_+(n)^2 = \frac{4}{5} $$ He might not be the first to notice this, even if I exclude my mentor who came up with the main conjecture and related ones. (I think it was also mentioned on chat and comments on MSE) Anyways it is also a nice conjecture. Is it equivalent ? No. Lets use shorthand notations : $x = \sup f_-(n), y = \inf f_+$. Then combining both conjectures (the original and the "Richard" variant) we get $$x y = \frac{5}{4} , x^2 - y^2 = (x-y)(x+y) = \frac{4}{5}$$ Now this implies we can compute the value of x (or y). We get an interesting situation here. If 2 conjectures are true than so is the third : $$x y = \frac{5}{4}$$ $$ x^2 - y^2 = (x-y)(x+y) = \frac{4}{5} $$ x is the positive real solution to $5 * 4^2 x^4 - 4^3 x^2 - 5^3 $ or $80 x^4 - 64 x^2 - 125$. NOTICE the 5's and 4's all over again. (or closed form for $x = \frac{1}{2} \sqrt {\frac{8 + \sqrt {689}}{5}}$) ($689 = 13*53$ if that matters to anyone) This was all known in the $90's$ by my mentor. I call it the Raes-Stanley conjecture. Update ! I had a talk with my mentor why he did not mention the $$ \sup f_-(n)^2 - \inf f_+(n)^2 = \frac{4}{5} $$ part of the Raes-Stanley conjecture. Although he noticed the apparant identity, he does not actually believe that last part. He said that the value converges fast for $n,m > 210000$ to $$ \sup f_-(n)^2 - \inf f_+(n)^2 = \frac{3.999789007..}{5} $$ In fact increasing n,m from 210000 to 314314 both gives $$ \sup f_-(n)^2 - \inf f_+(n)^2 = \frac{3.999789007..}{5} $$ so barely any noticeable change, while $$\sup f_- (n) \inf f_+ (m) = \frac{5}{4} $$ seems already heuristically confirmed. Testing for n,m smaller than 100000 might give the wrong impression and might be the cause of the mistake. Numerical coincidence might then lead to wrong conclusions. Roundoff errors might create an effect in the computations but he does not believe the "Stanley part " $$\sup f_- (n) \inf f_+ (m) = \frac{5}{4} $$ can be saved by those errors. If anyone can prove or argue or compute a higher value than $\frac{3.999789007..}{5}$, please inform me. Finally the Full Raes conjecture is the slight generalization : Let $f_- (n) = \Pi_{i=0}^n (\sin(i) - \frac{5}{4}) $ And let $ f_+(m) = \Pi_{i=0}^m (\sin(i) + \frac{5}{4}) $ It appears that $$\sup f_- (n) \inf f_+ (m) = \frac{5}{4} $$ and $$\inf |f_- (n)| \sup f_+ (m) = \frac{5}{4} $$ Why is that so ? $|*|$ means the absolute value here. Indeed $$\inf |f_- (n)| = 0.157559...$$ $$\sup f_- (n) = 1.308592...$$ $$\inf f_+ (n) = 0.955225...$$ $$\sup f_+ (n) = 7.933553...$$ $$0.955225... * 1.308592... = 1.25 = \frac{5}{4}$$ $$0.157559... * 7.933553... = 1.25 = \frac{5}{4}$$ Let $g_- (n) = \Pi_{i=0}^n (\cos(i) - \frac{5}{4}) $ And let $ g_+(m) = \Pi_{i=0}^m (\cos(i) + \frac{5}{4}) $ It appears that $$\sup g_- (n) \inf g_+ (m) = \frac{3}{4} $$ and $$\inf |g_- (n)| \sup g_+ (m) = \frac{3}{4} $$

Lower bounds (or less) for the period of sqrt(D) and related sequences

This is a continuation of Lower bounds for period length of continued fraction of square root which is a continuation of Upper bound of period length of continued fraction representation of very composite number square root. Yesterday, I came across a nice article with many problems on continued fractions of Michel Mendes France (from 1993): http://retro.seals.ch/digbib/fr/view?rid=ensmat-001:1993:39::498&id=&id2=&id3= (broken link) In problem 6 he asks: Let x be quadratic irrational and $\pi(x)$ the length of its period. Is $sup_n(\pi(x^n))=\infty$? Is this problem still open? I saw many articles about upper bounds for $\pi(\sqrt{D})$ but none on lower bounds (expect the Golubeva one that is mentioned in the first mentioned question, but due to lack of background, I fail to understand the results there). As Will Jagy asked: Do we even know whether $[\pi(\sqrt{n})):n\in \mathbb N]$ is bounded or not?

Open questions about posets

Partially ordered sets (posets) are important objects in combinatorics (with basic connections to extremal combinatorics and to algebraic combinatorics) and also in other areas of mathematics. They are also related to sorting and to other questions in the theory of computing. I am asking for a list of open questions and conjectures about posets.

Open problems in Sobolev spaces

What are the open problems in the theory of Sobolev spaces? I would like to see problems that are yes or no only. Also I would like to see problems with the statements that are short and easy to understand for someone who has a basic knowledge in the theory, say at the level of the book by Evans and Gariepy. The problems do not have to be a well know ones. Just the problems you think are interesting. Please, list each problem as a separate answer. That will allow people to leave comments related exclusively to this particular problem. I have been working with Sobolev spaces for most of my adult live and I have some of my favorite problems that I will list below. But I will do it later, because first I would like to see your problems.

Smallest area shape that covers all unit length curve

On a euclidean plane, what is the minimal area shape S, such that for every unit length curve, a translation and a rotation of S can cover the curve. What are the bounds of the shape's area if this is a open problem? When I asked this problem few years ago, someone told me it's open. I don't know if this is still open and I can't find any reference on it. I don't even know what branch of mathematics it falls under. so I can't even tag this question.

Symmetric function transition matrix and a non-conjecture by Clifford and Stanley

Consider the transition matrix $R = \left(R_{\lambda,\mu}\right)$, defined by $$ p_\lambda = \sum_{\mu} R_{\lambda\mu}m_\mu , $$ between the power-sum and the monomial basis of the ring of symmetric functions. There are plenty of combinatorial descriptions of $R_{\lambda\mu}$, it is for example the number of ordered brick-tableaux of shape λ and brick-sizes determined by μ, see e.g. this excellent paper with transition matrices by Eğecioğlu and Remmel. In the paper on Bottom Schur functions by P. Clifford and R. Stanley (2004), the authors consider the dimension of the null-space of $R-D$, where D is the diagonal of R. As the size n of the partitions increase, they computed (by computer I presume) the sequence of dimensions $d(n)$ is $$ 1 , 1 , 1 , 2 , 2 , 3 , 4 , 5 , 7 , 9 , 11 , 15 , 19 , 24 $$ but they do not make any conjecture of what this sequence of integers might be. However, a quick search in OEIS gives one result, A129528, entered in 2007, after Clifford and Stanley's paper was published. The sequence A129528, $a(n)$ is defined as follows: Consider the set of all Dyck paths, consisting of steps $(1,1)$ and $(1,-1)$. The peak-abscissa-sum of a path is the sum of the x-coordinates of all peaks. Then $a(n)$ is the number of Dyck paths of any length with peak-abscissa-sum n. Question: Is there some neat way to show that A129528 is at least a lower bound of $d(n)$, by explicitly constructing $a(n)$ linearly independent vectors in the null-space? A good start is to examine the Bottom Schur functions defined in the paper, as they can be identified with elements in the null space of $R-D$.

V3-018220 | MO-326199

Open problems concerning all the finite groups

What are the open problems concerning all the finite groups? The references will be appreciated. Here are two examples: Aschbacher-Guralnick conjecture (AG1984 p.447): the number of conjugacy classes of maximal subgroups of a finite group is at most its class number (i.e. the number of conjugacy classes of elements, or the number of irreducible complex representations up to equiv.). K.S. Brown's problem (B2000 Q.4; SW2016 p.760): Let G be a finite group, μ be the Möbius function of its subgroup lattice $L(G)$. Then the sum $\sum_{H \in L(G)}\mu(H,G)|G:H|$ is nonzero. There are two types of problems, those involving an upper/lower bound (like Aschbacher-Guralnick conjecture) and those "exact", involving no bound (like K.S. Brown's problem). I guess the first type is much more abundant than the second, so for the first type, please restrict to the main problems.

Is the exact solution of the wave equation for the scattering of waves by a disk/cylinder an open problem?

The solution exact solution of the Helmholtz equation for the scattering of waves by a sphere is relatively straightforward and has been known since the time of Lord Rayleigh. The exact solution of the wave equation for scattering of waves by a sphere is much trickier and has been dealt with in two relatively recent papers - here and here. I have been trying to determine whether there exists an exact solution for the wave equation in the two-dimensional case, i.e. for a disk/cylinder. It is not mentioned in the recent papers I listed above for the case of the sphere, and I haven't been able to find anything despite an extensive search of the literature. Does anyone know if an exact solution of the wave equation for the scattering of waves by a disk/cylinder exists, or is this still an open problem?

Seeking proof of the Cuckoo Cycle Conjecture

Allow me to introduce the Cuckoo Cycle Proof of Work, and conclude with a closely related Conjecture about random graphs, which I hope someone can find a proof for. Cuckoo Cycle is named after the Cuckoo Hashtable, in which each data item can be stored at two possible locations, one in each of two arrays. A hash function maps the pair of item and choice of array to its location in that array. When a newly stored item finds both its locations already occupied, one is kicked out and replaced by the new item. This forces the kicked-out item to

move to its alternate location, possibly kicking out yet another item. Problems arise if the corresponding Cuckoo graph, a bipartite graph with array locations as nodes and item location pairs as edges, has cycles. While n items, whose edges form a cycle, could barely be stored in the table, any $n+1$st item mapping within the same set of locations (a chord in the cycle) would not fit, as the pigeonhole principle tells us. In the Proof-of-Work problem, we typically set $n \ge 29$, and use edge indices (items) $0 \dots N-1$, where $N = 2^n$. The endpoints of edge i are (siphash(i|0) % N, siphash(i|1) % N), with siphash being a popular keyed hash function. A solution is a cycle of length L in this bipartite Cuckoo graph, where typically $L = 42$. Cuckoo Cycle solvers spend nearly all cycles on edge trimming; identifying and removing edges that end in a leaf node (of degree 1), as such edges cannot be part of a cycle. Trimming rounds alternate between the two node partitions. The fraction f_i of remaining edges after i trimming rounds (in the limit as N goes to infinity) appears to obey The Cuckoo Cycle Conjecture: $f_i = a_{i-1} * a_i$, where $a_{-1} = a_0 = 1$, and $a_{i+1} = 1 - e^{-a_i}$ f_i could equivalently be defined as the fraction of edges whose first endpoint is the middle of a (not necessarily simple) path of length $2i$. So far I have only been able to prove the conjecture for $i \le 3$. For instance, for i = 1, the probability that an edge endpoint is not the endpoint of any other edge is (1-1/N)N-1 ~ 1/e. Here's hoping someone finds an elegant proof...

Cyl(E) = Borel(E) for E non-reflexive Grothendieck Banach space

This is sort of a follow-up to Borel(X) = \sigma(X') for X non-separable PROBLEM: Given a Banach space E over $\mathbb{K} \in \{\mathbb{C}, \mathbb{R}\}$ that has the Grothendieck property. Does $\hat{C}(E) = \mathcal{B}(E)$ imply E is reflexive? (This would in turn imply that E is separable). Some definitions: A Banach space is a Grothendieck space if a sequence in E' which is $\sigma(E', E)$-convergent is automatically $\sigma(E', E'')$-convergent. Or equivalently: every $\sigma(E', E)$ zero sequence has subsequence which is $\sigma(E', E'')$-convergent, or equivalently: every linear, bounded operator from E to c_0 (or any separable Banach space) is automatically weakly compact. The σ-algebra $\hat{C}(E)$ is the σ-algebra generated by sets of the form $\mathcal{C}_{u_1, \cdots, u_n; C} := \{x \in E : (u_1(x), \cdots, u_n(x)) \in C\}$ where $u_1, \cdots, u_n \in E'$, $C \in \mathcal{B}(\mathbb{K}^n)$ and $n \in \mathbb{N}$. Notes: The σ-algebra $\hat{C}(E)$ equals the σ-algebra of weak Baire sets $\mathcal{B}_0(E, \sigma(E, E'))$ for every locally convex space E (see [2], Theorem 2.3). The inclusion $\hat{C}(E) \subset \mathcal{B}(E)$ is trivially true. If E is separable then $\hat{C}(E) = \mathcal{B}(E)$. [To see this use the Hahn-Banach theorem to show that $\mathcal{B}_E \in \hat{C}(E)$. As translations and scalar multplications are measurable with regard to the cylindrical σ-algebra the other inclusion follows.] A reflexive space is automatically Grothendieck. For a separable Grothendieck space E we have that the identity is weakly compact so E becomes reflexive A reflexive space E with $\hat{C}(E) = \mathcal{B}(E)$ is automatically separable ([1], Prop. 2.6, p.19). Without reflexivity the equality $\hat{C}(E) = \mathcal{B}(E)$ does not imply E is separable in general. The example $E = \ell^2(\mathbb{R})$ shows that there is a reflexive and non-separable space with $\mathcal{B}(E) \not= \hat{C}(E)$ Edgar's example below or $E = \ell^{\infty} = C(\beta \mathbb{N})$ gives a non-reflexive Grothendieck space with $\mathcal{B}(E) \not= \hat{C}(E)$. The question therefore: does every non-reflexive Grothendieck space have that property? There are non-reflexive Grothendieck spaces which do not contain ℓ^{∞} (cf. [3]). So we can't simply reduce to this case. I don't know much more about Grothendieck spaces though or characterizations of them that might be helpful. REFERENCES: [1] N. N. VAKHANIA, V. I. TARIELADZE, S. A. CHOBANYAN, Probability Distributions on Banach Spaces, Mathematics and its applications (D. Reidel Publishing Company), 1987 [2] http://www.iumj.indiana.edu/IUMJ/FULLTEXT/1977/26/26053 [3] R. HAYDON, A non-reflexive Grothendieck Space that does not contain ℓ^{∞}, Israel Journal of Mathematics, Vol 40, No. 1, 1981 EDIT: I rephrased the question and added some information.

Coloring a graph formed by cliques sharing at most one point

Consider a graph formed by k k order cliques sharing at most one point. Consider thedegenerate case of all cliques disjoint, which is trivially k colorable. Now, to colour any other such graph, we first color any one clique. Now, if any vertex of the colored clique is shared by m cliques, then, we could put at maximum $k-(m-1)$ vertices to expand the color class containing that vertex, which are chosen one from each clique not sharing that vertex. Such a vertex exists, by construction(as otherwise, other cliques would be sharing that vertex) . This corresponds to the number of reduced vertices from k^2 vertices, which is the degenerate case of all cliques being disjoint. Proceeding so on for all vertices of the colored clique, I think we can cover all the vertices of the graph by expanding the color classes to the required deficiency. Thus, the graph as a whole would be $k-$ colorable. Is the above assertion right? Or are there any counterexamples? Any light on this. Thanks beforehand.

Two commuting mappings in the disk

Suppose that f and g are two commuting continuous mappings from the closed unit disk (or, if you prefer, the closed unit ball in R^n) to itself. Does there always exist a point x such that $f(x)=g(x)$? If one of the mappings is invertible, then it is just a restatement of Brouwer's fixed point theorem but I do not know the answer in the general case and would not even dare to guess what it must be. Also, the answer is well-known to be "Yes" in dimension 1.

Hilbert 16th problem and dynamical Lefschetz trace formula

I would like to apply the known version of the conjectural formula (11) page 10 of the paper Number theory and dynamical Lefschetz trace formula. Disclaimer: I do not have a complete understanding of this formula but I can get an sketch of it. I just know that both sides of the formula are not number but distribution. I also know the meaning of ingredient of the formula. I wish to apply it to find an appropriate application in limit cycle theory. To start this way, I have three precise questions: Question 1: In the right hand side of the formula (11), is not necessary to assume that there are only a finite number of non degenerate periodic orbits γ(As they are appeared in the sum $\sum$ of the right side of the formula)? Is it implicitly included in the assumptions of that formula? I think that even the non degeneracy assumption of periodic orbits does not easily imply the finite ness of such periodic orbits. Is not possible that a sequence of non degenerate periodic orbits accumulate to a non periodic orbit which is a kind of complicated and strange attractor? Question 2:(This question is completely different from the previous one but there are some motivations from this posts And also this post Lifting a Quadratic System to a non Vanishing vector field on S^3) A polynomial vector field on the plane gives us an analytic vector field X on S^2. Put $\tilde{X}$ for the obvious lifting of X on $S^2\times S^1$ with $\tilde{X}=X+\partial/\partial{\theta}$ Is there a quadratic polynomial vector field on $\mathbb{R}^2$ with Poincare compactification X such that $\tilde{X}$ on $S^2\times S^1$ does not admit a 2 dimensional transversal foliation which is invariant under the flow of $\tilde{X}$. The reason we consider Quadratic system: Note that every quadratic system is a geodesible vector field but it is not the case for higher degree polynomial vector field. On the other hand, in dimension 2, if a vector field X is geodesible then there is a transversal field Y with $[X,Y] \parallel Y$ this implies that orbits of Y are invariant under flow of X. So this make us to be hopeful a little that the product vector field $\tilde{X}=X+\partial/\partial \theta$ admit a transversal 2 dimensional foliation which is invariant under the flow of $\tilde{X}$. Existence of such transversal foliation is the key condition in the paper we linked in the first lines of this post. The reason we consider $S^2\times S^1$ rather than S^3: The lifting of the simplest vector field $X=0$ to the Hopf vector field on S^3 does not admit a transversal foliation. Question 3: When we lift a vector field X to a non vanishing vector field $\tilde{X}$ on $S^3, S^2\times S^1\quad\text{or}\quad T^1 S^2$, it is possible that the preimage of a closed orbit, which is an invariant torus, would not contain any closed orbit, so we loose our closed orbits.please see the comment by Sebastian Goette in this post. With terminologies in the linked paper, let we have a 3 manifold foliated by 2 dimensional leaves whch is compatible with a flow X. So is there an analogy of the formula (11) in page 10 of the linked paper in the first lines of this post whose right side depends on invariant torus of X as well as closed orbits of X? Remark: The concept "Blue Sky catastrophe" and difficulties occured in "Finitness theorem for Limit Cycles" are motivations for the first question of this post.

Razborov's response to Almost Natural Proofs

This post is about Natural Proofs barrier in computational complexity. There are two recent papers related to this. They are: Amplifying lower bounds by means of self-reducibility by Eric Allender and Michal Koucký, Almost-natural proofs by Timothy Chow. Alexander Razborov mentioned them at the end of his talk in the first Barriers Workshop at IAS in 2009. The video of his talk is available here. He mentioned that a possible way to respond to these would be to make the largeness condition relative. So here is my question: Has there been any progress on this?

An triangle inequality $\sum_{i=1}^n b_i^\alpha \ge \sum_{i=1}^na_i^\alpha $ if $\alpha >1$

Using my computer I discovered that: if a,b,c are sidelengths of a triangle, then $(a+b-c)^\alpha+(b+c-a)^\alpha+(c+a-b)^\alpha \ge a^\alpha+b^\alpha+c^\alpha $ if $\alpha >1$ $(a+b-c)^\alpha+(b+c-a)^\alpha+(c+a-b)^\alpha \le a^\alpha+b^\alpha+c^\alpha $ if $0< \alpha <1$ My question: The generalization inequality as follow is corect? Let and $\alpha>0$, $a_i>0$ for $i=\overline{1,n}$ and $S=a_1+a_2+....+a_n$. Let $b_i=S-(n-1)a_i \ge 0$ for $i=\overline{1,n}$, then $\sum_{i=1}^n b_i^\alpha \ge \sum_{i=1}^na_i^\alpha $ if $\alpha >1$ $\sum_{i=1}^n b_i^\alpha \le \sum_{i=1}^na_i^\alpha $ if $0< \alpha <1$

A cohomology associated to a (not necessarily integrable) distribution (Hilbert 16th problem and dynamical Lefschetz trace formula 2)

Let (M,D) be a pair consisting of a manifold M and a distribution D on M. The de Rham complex $\Omega^*(M)$ has the following subcomplex $$\Omega^*(M,D)=\{ \alpha \in \Omega^*(M)\mid \alpha_{| D}=d\alpha_{|D}=0\}.$$ When D is an integrable

distribution, the last condition $d\alpha_{|D}=0$ is redundant. The quotient complex $\Omega^*(M)/\Omega^*(M,D)$ produces a cohomology. In this complex we can replace the space of coboundaries(exact forms along distribution) with its smooth topology closure. The reason for closure is explained in this paper which is linked in the MO post in the next paragraph. So we get a cohomology $H^*(M,D)$, the cohomology of M along distribution D. Now assume that the flow of a vector field $\tilde{X}$ on M preserves D. Is the dynamical Lefschetz trace formula discussed in "Hilbert 16th problem and dynamical Lefschetz trace formula" still valid? Motivation: Theorem 9.3 page 29 of the following paper says that if a vector field on S^3 is transversal to a codimension one foliation, then the vector field must have a parameter family of periodic orbits. On the other hand one of the main concerns of the above MO post is finiteness of closed orbits for a vector field on S^3 which is a result of lifting of a (generic) vector field on 2-sphere. So we should almost give up finding a foliation transversal to our vector field. Instead of a foliation, we search a (non integrable) transversal distribution which is preserved by the flow of our vector field. So we need an appropriate analogy of leafwise de Rham cohomology when there is not any leaf, that is a non-integrable distribution. The above cohomology we introduce is a candidate for such appropriate cohomology. So we hope that the lifting $\tilde{X}$ (to S^3 or $S^2\times S^1$) of a Poincare compactification of a quadratic plannar vector field would be a geodesible vector field. Then the orthogonal direction D(with respect to an appropriate metric adapted to $\tilde{X}$) is obviously preserved by flow of $\tilde{X}$. (For more explaination on the later paragraph please see [this post](Finding a 1-form adapted to a smooth flow) So we try to investigate the dynamics of $\tilde{X}$ via a possible distribution analogy of Dynamical trace formula). Precise and detailed motivations are mentioned in the above linked MO post entitled "Hilbert 16th problem and dynamical Lefschetz trace formula".

V3-018233 | MO-33796

Existence of a pseudo-polynomial time algorithm for a counting problem.

Let T={1,...,n} be a set of tasks. Each task i has associated a non negative processing time p_i and a deadline d_i. A feasible schedule of the tasks consists of a permutation of n elements pi, such that \sum_i=1^k p_(pi(i)) <= d_(pi(i)) for all k=1,...n. Does there exists a pseudo-polynomial time algorithm for computing the total number of feasible schedules? A pseudo-polynomial time algorithm is an algorithm whose running time is bounded by a polynomial on the size of the input, given that the input is written in unary notation (2=II, 3 =III). (e.g., the size of a number n in unary notation is O(n), and not O(log(n)). This is an open question from an article published in 2009 at Operations Research Letters.

The Total Graph is similar to a line graph

Consider the total graph of a regular graph. From the structure, it seems that it has a similar structure to the line graph (two different sub-cliques joining at a single point) except that, in addition, there is an edge between two different sub-cliques. Note that the sub-cliques in the total graph are the just the sub-cliques which are present in the line graph of the graph with a vertex added to each sub-clique make it adjacent to all the vertices of a particular sub-clique, thereby increasing the order of the sub-cliques by one. This means that the clique number of the total graph of a graph is one more than the clique number of the line graph of the same graph. This leads me to infer that the total graph of a graph has similar chromatic properties as a line graph of a graph. Specifically, I expect the total graph of a graph to satisfy a similar bound to Vizing's theorem for line graphs. Will this be true? Thanks beforehand.

Is the conjecture $min(A,B) \le rad(ABC)$ new and correct?

$\DeclareMathOperator\rad{rad}$Conjecture: If A, B, C are positive integers with $\gcd(A, B)=1$, $\gcd(B, C)=1$, and $\gcd(C, A)=1$, and if $A+B=C$, then $\min(A,B) \le \rad(ABC)$. If the conjecture is valid, then we can use the conjecture to prove the Fermat last theorem as follows: Proof of the Fermat last theorem: We consider the Fermat equation: $x^n+y^n=z^n$ with $\gcd(x, y)=1$, $\gcd(y, z)=1$, and $\gcd(z, x)=1$. There is no loss of generality in assuming that $x \le y <z$. By the conjecture, we get $x^n \le \rad(x^n y^n z^n)=\rad(x y z)\le x y z $. So $x^n+y^n \le xyz+y^n<z^3+(z-1)^n$. But we can easily prove that $z^3+(z-1)^n < z^n$ whenever $n > 3$ and $z>1$. So now we only need to prove the Fermat last theorem with $n=3$. My question: Is the conjecture above new and correct?

Which knot invariants have no known diagram-independent descriptions?

Many knot invariants in knot theory are discovered by finding a property of knot diagrams which is invariant under the three Reidemeister moves. Now in principle, any knot invariant can be described in a diagram-independent way, that is, as a property of the three-dimensional knot itself without reference to diagrams of the knot. But in practice, it can take years between the development of a knot invariant and the discovery of a diagram-independent description of it. So my question is, for what knot invariants is a diagram-independent description not yet known?

What is the state of research on finding all prime knots with 17 crossings?

In this 1998 journal paper, all the prime knots with 16 or fewer crossings are found (some of which were found earlier by others). There are over 1.7 million such knots. But the prime knots with 17 crossings have not yet been tabulated. Here is what this book says: This is probably hard and requires new ideas. But this book was written in 2004, so things may have changed since then. There have certainly been a lot of developments in knot theory over the past 15 years. So my question is, what is the state of research on finding all prime knots with 17 crossings? Are we relatively close to doing so, and have partial results been discovered?

Can we cover the unit square by these rectangles?

The following question was a research exercise (i.e. an open problem) in R. Graham, D.E. Knuth, and O. Patashnik, "Concrete Mathematics", 1988, chapter 1. It is easy to show that $$\sum_{1 \leq k } \left(\frac{1}{k} \times \frac{1}{k+1}\right) = \sum_{1 \leq k } \left(\frac{1}{k} - \frac{1}{k+1}\right) = 1.$$ The product $\frac{1}{k} \times \frac{1}{k+1}$ is equal to the area of a $\frac{1}{k}$by$\frac{1}{k+1}$ rectangle. The sum of the areas of these rectangles is equal to 1, which is the area of a unit square. Can we use these rectangles to cover a unit square? Is this problem still open? What are the best results we know about this problem (or its relaxations)?

What's an example of an ∞-topos not equivalent to sheaves on a Grothendieck site?

My question is as in the title: Does anyone have an example (supposing one exists) of an ∞-topos which is known not to be equivalent to sheaves on a Grothendieck site? An ∞-topos is as in Higher Topos Theory (HTT) 6.1.0.4: an ∞-category which is an accessible left-exact localization of presheaves on a small ∞-category. A Grothendieck site is a small ∞-category $\mathcal{C}$ equipped with the ∞-categorical variant of the classical notion of a Grothendieck topology $\mathcal{T}$, as in HTT 6.2.2: a collection of sieves (subobjects $U\to j(C)$ of representable presheaves on $\mathcal{C}$) satisfying some axioms. Sheaves on $(\mathcal{C},\mathcal{T})$ are presheaves of ∞-groupoids on $\mathcal{C}$ which are local for the sieves in $\mathcal{T}$. Such form a full subcategory $\mathrm{Shv}(\mathcal{C},\mathcal{T})$ of the ∞-category of presheaves. Note: the question Examples of $(\infty,1)$-topoi that are not given as sheaves on a Grothendieck topology appears superficially to be equivalent to this one. In practice it is not exactly the same. As answers to that question show, many interesting ∞-topoi exist which can be described without reference to any Grothendieck site. But it is still conceivable that a suitable site exists. Also note: any ∞-topos $\mathcal{X}$ can be obtained as an accessible left-exact localization of some $\mathrm{Shv}(\mathcal{C},\mathcal{T})$ with respect to a suitable class of ∞-connected morphisms (HTT 6.2.2, 6.5.3.14), e.g., the class of hypercovers. However, this does not immediately preclude $\mathcal{X}$ being equivalent to $\mathrm{Shv}(\mathcal{C}',\mathcal{T}')$ for some other Grothendieck site

$(\mathcal{C}',\mathcal{T}')$. Added remark. I asked this question because I had, for a long time, tacitly assumed that such examples were plentiful, until I thought about it and realized I had no basis for thinking that. As no answers have yet been given, and I'm not aware of any tools which would likely lead to a resolution one way or the other, it looks to me that this should be regarded as an open question.

Is it an open problem whether fast-growing hierarchies can be defined without fundamental sequences?

Googology Wiki says this, concerning the relation between fast-growing hierarchies defined for all countable ordinals, and the existence of a system of assigning a canonical fundamental sequence to each countable limit ordinal: It is an open problem whether an ordinal hierarchy can be defined without using fundamental sequences. More explicitly, the problem concerns whether there is a model of ZF such that there exists an $F : \omega_1 \rightarrow (\mathbb{N} \rightarrow \mathbb{N})$ where for all $\alpha > \beta, F(\alpha)$ eventually outgrows $F(\beta)$, but there does not exist an $S: \omega_1 \cap \text{Lim} \rightarrow (\mathbb{N} \rightarrow \omega_1)$ such that for all $\alpha, \sup(R) = \alpha$ where R is the range of $S(\alpha)$. My question is, is it true that the question of whether there exists such a model of ZF is an open problem?

Permute Wada Lakes keeping the coastline intact? (still open in dim >2)

Wada Lakes are three disjoint open subsets of $\mathbb R^2$ with common boundary. Originally they were constructed by hand, but they also arise naturally in the real life, that is, theory of dynamical systems. (See, for example, this http://www.math.cornell.edu/~hubbard/pendulum.pdf paper of John Hubbard.) From dynamical construction it is clear that one can have a homeomorphism that permutes the lakes. For example, this expository paper http://www.ams.org/notices/200601/fea-coudene.pdf gives such a homeomorphism (in fact, a diffeomorphism) for lakes on the sphere S^2. The dynamics on the boundary of the lakes is chaotic. == Question 1: Let U_1, U_2 and U_3 be open subset of $\mathbb R^d$ with common boundary C. Assume that each U_i is an image of an injective continuous map $\mathbb R^d\to\mathbb R^d$. Is there a homeomorphism of $\mathbb R^d$ that permutes open sets U_i and is identity on C? Question 2: Let $U_i\subset \mathbb R^d$, $i\in \mathbb Z$, be a disjoint collection of open sets each of which is homeomorphic to $\mathbb R^d$. Is there a homeomorphism of $\mathbb R^d$ that satisfies the following h maps U_i onto U_{i+1} every point in ∂U_i is periodic under h == Edit: Below André Henriques has produced two examples when such a homeomorphism does not exist. Both examples make use of some local structure that cannot be permuted. It is still not clear what happens for "abstact Wada Lakes": are these examples exceptions or arbitrary Wada Lakes cannot be permuted as well? Edit2 (Jan. 9th 2012) In is clear now that there is no such homeomorphism if the dimension $d=2$. (See the comments below). The answer to Q1 is also negative in higher dimension as explained in the reference given by Andres Koropecki. For $d\ge 3$ there are examples by André Henriques of open sets for which one cannot find such a homeomorphism. In general, Question 2 is still open.

Do torsion-free groups give projectionless group ($C^\ast$) algebras?

One of the reasons I study von Neumann algebras is that they always have plenty of projections. There are many projectionless $C^\ast$-algebras (0 and possibly 1 are the only projections), but the von Neumann algebras they generate must have nontrivial projections (unless it's just the complex numbers, of course). A good example of this is the reduced group $C^\ast$-algebra of any free group F_n. If $n=1$, then $C_r^\ast(Z)\cong C(S^1)$ via the Gelfand transform, which is clearly projectionless. If $n\geq 2$, the proof is fairly complicated. See Davidson's book for a proof when $n=2$. If G is a torsion-free group, is the reduced group $C^\ast$-algebra of G projectionless? This $C^\ast$-algebra always contains the group algebra $C[G]$, so a simpler question is whether $C[G]$ is projectionless if G is torsion-free. Note that torsion-free is a necessary condition as one gets a projection from summing up the elements in the cyclic group generated by a torsion element and dividing by the order of the element. EDIT: changed typestting. still some bugs... help please?

Is every finite-order unimodular matrix conjugate to a $0,1,-1$ matrix?

Problem. Given a matrix $A\in\mathrm{GL}(n,\mathbb{Z})$ such that $A^k=1$ for some $k\geq 1$, is there a matrix $g\in\mathrm{GL}(n,\mathbb{Z})$ such that gAg^{-1} has only 0, 1, and -1 as possible entries? Edit: after the remark by Mark Sapir that it is a famous open problem (which for me was already sufficient as an answer), I changed my question into the following ones, so now maybe it is more suitable for staying on MO without being closed. What is known about this problem? Which other parts of mathematics is it connected to?

When do two knots have isomorphic fundamental bikeis?

A kei, also known as an involutive (or involutory) quandle, is a quandle $(Q,*)$ satisfying the involution condition that $(x*y)*y=x$ for all x and y. Just like we can define a fundamental quandle of a knot using arcs of an oriented knot diagram, we can define the fundamental kei of a knot using arcs of an unoriented knot diagram. A bikei, also known as an involutive biquandle, is a biquandle satisfying similar involution conditions. Just as we can define the fundamental biquandle of a knot using semiarcs of an oriented knot diagram, we can define the fundamental bikei of a knot using the semiarcs of an unoriented knot diagram. (These are all defined precisely in Elhamdadi and Nelson's book Quandles: An Introduction to the Algebra of Knots.) My question is, under what circumstances are the fundamental bikeis of two knots isomorphic? Now this thesis Martina Vaváčková, Algebraic Structures for Knot Coloring, Masters thesis, Charles University (2018) (abstract page, pdf) shows that the fundamental keis of the granny knot and square knot are isomorphic, whereas their fundamental quandles are not isomorphic. The recent journal paper Katsumi Ishikawa, Knot Quandles vs. Knot Biquandles, International Journal of Mathematics (accepted to appear) doi:10.1142/S0129167X20500159, on the other hand, shows that the fundamental biquandles of two knots are isomorphic if and only if their fundamental quandles are isomorphic. So this raises two natural questions: Can two knots have isomorphic fundamental bikeis without having isomorphic fundamental biquandles? And can two knots have isomorphic fundamental keis without having isomorphic fundamental bikeis? Note that the answers to both can't be no since isomorphic fundamental keis don't imply isomorphic fundamental quandles. (The converses are clear: isomorphic biquandles imply isomorphic bikeis, and isomorphic bikeis imply isomorphic keis.) Do the two results I mentioned shed any light on these questions? Are either of these questions open problems?

Conjugacy classes and reduced group C^*-algebra of an amenable group

The reduced C^*-algebra of a non-abelian free group G has a unique trace. Hence, there is no chance to separate conjugacy classes of group elements using traces on $C^\star_{red} G$. On the other side, for the group ${\mathbb Z}$, separation is clearly possible. Question: Let G be an amenable group. Does the reduced group $C^\star$-algebra of G support sufficiently many traces to distinguish between conjugacy classes of group elements? EDIT: The question seems already interesting for $S_{\infty} = \cup_n S_n$. Let's get explicit and pick $g \in S_n$ (for some n) and consider the canonical trace $\tau_{g,n}$ which sends every conjugate of g to 1 and all other elements to zero. (This can be done for any $n' \geq n$ since $S_n \subset S_{n'}$.) The function $\tau_{g,n} \colon {\mathbb C}S_n \to {\mathbb C}$ is a conjugation invariant function and hence, it must be a linear combination of the normalized traces of irreducible representations of S_n. Question: What is the sum of the absolute values of the coefficients that come up in this linear combination of traces? This is (as one can check) the norm of $\tau_{g,n}$, call it $c(g,n)$. So, we see that the compatible family of maps $\tau_{g,n}$ extends from ${\mathbb C}S_{\infty}$ to $C^* S_{\infty}$ if and only if $c(g,n)$ remains bounded.

How can an approach to P vs NP based on descriptive complexity avoid being a natural proof in the sense of Raborov-Rudich?

EDIT: This question has been modified to make it a stand-alone question. Feel free to retract your votes for the previous version. Here are Vinay Deolalikar's paper, and Richard Lipton's first post about it, and the wiki page on polymath site summarizing the discussions about it. His approach is based on descriptive complexity. One of famous barriers for separating NP from P is Razborov-Rudich Natural Proofs barrier. Richard Lipton remarked about his paper and the natural proofs barrier that apparently "it exploits a uniform characterization of P that may not extend to give lower bounds against circuits". A question which is mentioned in one of the comments on Lipton's post is: How essential is the uniformity of P to his proof? i.e is the uniformity of P used in such an essential way that the barrier will not apply to it? (By essential I mean that the proof does not work for the non-uniform version.) So here is my questions: Are there any previous computational complexity results based on descriptive complexity that avoid the Razborov-Rudich natural proofs barrier (because of being based on descriptive complexity)? How can an approach to P vs NP based on descriptive complexity avoid being a natural proof in the sense of Raborov-Rudich? A related question is: What are the complexity results using uniformity in an essential way other than proofs by diagonalization? Related closed MO posts: When would you read a paper claiming to have settled a long open problem like P vs. NP? https://mathoverflow.net/questions/34953/whats-wrong-with-this-proof-closed Discussion on meta: http://mathoverflow.tqft.net/discussion/590/whats-wrong-with-this-proof/

What impact would P!=NP have on the characterization of BQP?

Many complexity theorists assume that $P\ne NP.$ If this is proved, how would it impact quantum computing and quantum algorithms? Would the proof immediately disallow quantum algorithms from ever solving NP-Complete problems in Quantum Polynomial time? According to Wikipedia, quantum complexity classes BQP and QMA are the bounded-error quantum analogues of P and NP. Is it likely that a proof that $P\ne NP$ can be adapted to the quantum setting to show that $BQP \ne QMA?$

Conjectured primality test for specific class of $N=4kp^n+1$

Can you provide a proof or counterexample for the following claim? Let $P_m(x)=2^{-m}\cdot((x-\sqrt{x^2-4})^m+(x+\sqrt{x^2-4})^m)$. Let $N= 4kp^{n}+1 $ where k is a positive natural number , $ 4k<2^n$, p is a prime number and $n\ge3$.

Let a be a natural number greater than two such that $\left(\frac{a-2}{N}\right)=-1$ and $\left(\frac{a+2}{N}\right)=-1$ where $\left(\frac{}{}\right)$ denotes Jacobi symbol. Let $S_i=P_p(S_{i-1})$ with S_0 equal to the modular $P_{kp^2}(a) \text{mod} N$. Then N is prime if and only if $S_{n-2} \equiv 0 \pmod{N}$. You can run this test here. I have verified this claim for $k \in [1,500]$ with $p \leq 97$ and $n \in [3,50]$. Further generalization of the claim A Let $P_m(x)=2^{-m}\cdot((x-\sqrt{x^2-4})^m+(x+\sqrt{x^2-4})^m)$. Let $N= 2kp^{n} + 1 $ where k is a positive natural number , $ 2k<2^n$, p is a prime number and $n\ge3$. Let a be a natural number greater than two such that $\left(\frac{a-2}{N}\right)=-1$ and $\left(\frac{a+2}{N}\right)=-1$ where $\left(\frac{}{}\right)$ denotes Jacobi symbol. Let $S_i=P_p(S_{i-1})$ with S_0 equal to the modular $P_{kp^2}(a) \text{mod} N$. Then N is prime if and only if $S_{n-2} \equiv -2 \pmod{N}$. You can run this test here. B Let $P_m(x)=2^{-m}\cdot((x-\sqrt{x^2-4})^m+(x+\sqrt{x^2-4})^m)$. Let $N= 2kp^{n} - 1 $ where k is a positive natural number , $ 2k<2^n$, p is a prime number and $n\ge3$. Finite-dimensional subalgebras of $C^\star$-algebras

Let A be a unital $C^\star$-algebra and let $a_1,\dots,a_n$ be a finite list of normal elements in A which (together with their adjoints) generate a norm-dense $\star$-subalgebra $B \subset A$. Clearly, if A is finite-dimensional, then every element in A (and hence B) has finite spectrum. I am asking for the converse. Question: Assume that each element of B has finite spectrum. Is it true that A has to be finite-dimensional? The existence of finitely-generated infinite torsion groups shows that this might be a highly non-trivial problem. In this case one would consider the reduced group $C^\star$-algebra and note that all monomials in the generators of the group and their inverses (which are equal to the adjoints of the generators) would have finite spectrum. However, the generated algebra would still be infinite-dimensional. I do not know of any simpler way to come up with such an example. In this case it is conceivable that the random-walk operator associated with the generating set (which is an element in the real group ring) has infinite spectrum, even though I did not prove this. Maybe there is also need to consider the spectra of elements in matrices over B (which of course follow to be finite if A is finite-dimensional.) In view of this, I am not only asking for an answer to the question but also for the right question (or a better one) if the answer to the original question is negative. A stronger assumption would be to assume that A itself consists only of elements with finite spectrum. This case seems much easier to approach and the answer seems to be positive. In fact every infinite-dimensional $C^\star$-algebra should contain an element with infinite spectrum. Just to get started, a more concrete instance of the question above is: Question: Let p_1, p_2 and p_3 be three projections in a C^*-algebra with the property that every (non-commutative) polynomial in p_1, p_2 and p_3 has finite spectrum. Is it true that the projections generate a finite-dimensional algebra?

Schur positive expression involving border-strip tableaux

Recall the power-sum expansion of Schur functions, $$ s_\lambda = \sum_\mu \chi^{\lambda}(\mu) \frac{p_\mu}{z_\mu}, $$ in terms of Sn-character. These can be calculated by the Murnaghan-Nakayama rule, stating that characters are a signed sum over border-strip tableaux: $$ \chi^{\lambda}(\mu) = \sum_{T \in BST(\lambda,\mu)} (-1)^{ht(T)} . $$ Now, what if we instead consider the 'cancellation-free' expression (yes, the omission of z_μ is intended): $$ CF_\lambda := \sum_\mu |BST(\lambda,\mu)| p_\mu. $$ Is the symmetric function CF_λ also Schur-positive? I have verified that this is the case for all $|\lambda| \leq 8$. This is the data for all λ with at most size 4. 1->ss[{1}] 2->2 ss[{2}] 11->2 ss[{2}] 3->3 ss[{3}]+ss[{2,1}]+ss[{1,1,1}] 21->5 ss[{3}]+3 ss[{2,1}]+ss[{1,1,1}] 111->3 ss[{3}]+ss[{2,1}]+ss[{1,1,1}] 4->5 ss[{4}]+3 ss[{2,2}]+2 ss[{3,1}]+2 ss[{2,1,1}]+ss[{1,1,1,1}] 31->10 ss[{4}]+6 ss[{2,2}]+10 ss[{3,1}]+6 ss[{2,1,1}]+2 ss[{1,1,1,1}] 22->7 ss[{4}]+7 ss[{2,2}]+6 ss[{3,1}]+2 ss[{2,1,1}]+3 ss[{1,1,1,1}] 211->10 ss[{4}]+6 ss[{2,2}]+10 ss[{3,1}]+6 ss[{2,1,1}]+2 ss[{1,1,1,1}] 1111->5 ss[{4}]+3 ss[{2,2}]+2 ss[{3,1}]+2 ss[{2,1,1}]+ss[{1,1,1,1}]

About semiprimal representations of 1

Conjecture A_1 : For every $m \in \mathbb N \setminus \{1\}$ there exist mutually different primes $p_{r_1},...,p_{r_m}$ and mutually different primes $b_{w_1},...,b_{w_m}$ and numbers $i_1,...,i_m \in \{1,2\}$ such that $$\displaystyle \sum_{k=1}^m (-1)^{^{i_k}}b_{w_k}p_{r_k}=1$$ Is this known to be true? If not known to be true, I conjecture it is true. According to your knowledge of the subject, is the number of representations infinite for all $m\geq 2$? This I would like to formulate as: Conjecture B : The number of representations is infinite for all $m \geq 2$ And, with the help and computational efforts of Peter it seems that the conjecture A_1 can be strengthened to: Conjecture A_2: For every $m \in \mathbb N \setminus \{1\}$ there exist mutually different primes $p_{r_1},...,p_{r_m}$ and mutually different primes $b_{w_1},...,b_{w_m}$ such that $$\displaystyle p_{r_1}b_{w_1-} \sum_{k=2}^m b_{w_k}p_{r_k}=1$$ Some observations and computations even suggest that in conjecture A_1 and A_2 there are examples where all the mutually different primes $p_{r_1},...,p_{r_m}$ also can be mutually different from all the mutually different primes $b_{w_1},...,b_{w_m}$. What is already known about these and similar problems?

Effective radius of section of a convex set compared to that of the convex itself

The effective radius $er(A)$ of a n-solid A, is defined by Schramm (see the question by Gil Kalai Volumes of Sets of Constant Width in High Dimensions) to be the radius of the n-ball that has the same volume. Question(s) : Let A be a n-convex (convex set in the n dimentionnal euclidian affine space $\mathbb A_n$) and H a hyperplane of $\mathbb A^n$ such that $B=A\cap H$ has maximal volume (resp. such that the boundary of $B'=A\cap H$ is maximal in volume) a) Is $er(B)\geq er(A) $? b) Is $er(B')\geq er(A)$? I think the answer (especially the b) question) if positive implies the resolution of the question in Volumes of Sets of Constant Width in High Dimensions podted by Gil Kalai. Let me try an heuristic for the first inequality, in 3 dimensions (I write vol(A) as well as for a volume or an area, as soon as there is no ambiguities) : Take $t\mapsto H_t$ a path of plans parallele to H that go throught C and that intersect C in B_t. Now we associate to B_t a disk D_t that radius is $er(B_t)$ such that its center is $t\in T$ and that T is a line. Consider $E=\bigcup_{t\in T} D_t$. It is clear that $Vol (E) = Vol (C)$. It is also clear that E is the π- rotation solid generated by , say E_0 : union of coplanar "effectives diameters" The question a) for dim 3 is then equivalent to : Is $vol(E_0)$ smaller then $vol(B)$? This would be automatically the case if E_0 can be isometrically embeded in C whom a greater section (in volume, well in this case "area") is B - it appears that the question that translate the possibility of this transversal embedding is : can we put the line T inside C and take in each "efficient disk" an "efficient diametre" inside C in such a way that they are co-planar.. we could imagine that there is some torsion around T that make this operation impossible, despite convexity condiderations... never the less, this intermediary request is stronger then the one of the (here part a) but also wrt part b)) question... The problem of this heuristic is not only the torsions phenomenons that I think they might not occure in 3 dim (and that we can probably get rid of, considering that the case that we are dealing with are well behaving, especially throught heredity) but the fact that I'm not sure it can be adapted to greater dimensions, because E_0 is 2-dimensional in any case... that does not go against the relevance of the questions but that does not give at least to me a clear hope or a clue, well maybe this discussion can be adapted to the general case... or not.

Which curves and surfaces are realizable by linkages? references?

Ok, so I try to formulate rigorously the question in the title, for which I am asking for references. My definitions may be flawed, so feel free to adjust/correct them! I care about dimensions 2 and 3 below, but feel free to mention general d as well. Let $d\ge 1$ be an integer, $G=(V,E)$ be a graph, $w:E\to [0, \infty)$ be a weight function. A realization in $\mathbb R^d$ with graph G and weight w is a map $P:V\to\mathbb R^d$ with the further property that $|P(v)-P(v')|=w(v,v')$ whenever $\{v,v'\}\in E$. I will identify such P with its image, I hope it's not a problem. Edit (May 11, 2020): As pointed out by Misha, this below definition is not correct. The action of isometries makes the set of all realizations of a linkage always cover all $\mathbb R^d$. He indicates a paper in which a more inclusive definition is formulated in $d=2$. (Previous "wrong" definition: I say that a set $A\subset \mathbb R^d$ is realizable by linkages if there exists G,w as above and an cover of A by open sets of $\mathbb R^d$ such that for every $U\subset\mathbb R^d$ in the cover there exist G,w such that that the union of all (images of) realizations of G,w in $\mathbb R^d$ intersected with U coincides with $A\cap U$.) To "fix the problem", following the we will allow a subset of vertices of G to be kept fixed in $\mathbb R^d$. In dimension 2 this apparently generalizes the definition in the above paper, but I think that the result of the paper still allows to reply positively to the $d=2$ case of the question, with little extra work. Revised definition: We say that $A\subset \mathbb R^d$ is realizable by linkages if there exists a cover of A by open sets of $\mathbb R^d$ such that for every $U\subset\mathbb R^d$ in the cover there exist $G=(V,E)$ and w as above, a subset $F\subset V$, and a map $\phi: F\to\mathbb R^d$, such that the union of all (images of) those realizations of G,w which restricted to F equal ϕ, intersected with U, coincides with $A\cap U$. Question: Say $d=2$ or $d=3$. Is it true that all algebraic sets $A\subset\mathbb R^d$ are realizable by linkages? What are references for this? (Note: as of May 11 2020, it appears to me that the case $d=2$ is nicely treated in the answers given, while the case $d=3$ is not yet treated, possibly due to the previously bad definition.) I found some mention of this, without references on Branko Grünbaum's "Lectures on lost mathematics", dated around 1975, and he says there that $d=2$ case is known, but does not give references, and $d=3$ case is a question by Hilbert which is open (but again no references there).

Basic research problems references

I have been looking for research problems in pure mathematics that I can try to solve for publishing papers. I am quite aware that it takes a lot of time and effort to get to a level where I can do some "serious" research work. Meanwhile, I was thinking that, may be, I can try to solve problems which are at the level of 1st year graduate level (or even Master's level). By "level", I mean that a 1st year grad student should know all the terms used in the paper. I understand that maintaining a list of unsolved/open problems is an extremely tough task and probably the best method is to look for journals/papers where authors include open/unsolved/extension of the problems. I would appreciate if you can include here: (i) List

of problems (I have also collected a list of unsolved/open problems from the internet which I would be happy to share here in one of the answers). (ii) Journals which concerns articles at the "level" mentioned above (For e.g. I hope that this list will exclude annals of math, Inventiones Mathematicae or any top journals which mostly include high level research papers. The American Mathematical Monthly is an excellent source.) Remarks: 1) I admit that it seems like a very vague question but I am also confident of the fact that many other fellow students are looking for such a source. If the community feels that it should be closed, I will also second it. 2) One of the great sources for finding research problems are conferences (or proceedings of ICM) where the leading researchers include open problems, but those problems, in my view, seem to be untouchable for most of the 1st year graduate students. 3) From one point view, there is a related question about letters in mathematics. This is definitely one of the answer I would have expected for this question. I will be glad to provide any details if needed. Kindly let me know if I should post this question somewhere else.

A constant bizarrely related to the Fibonacci Numbers

For roughly the past month, I have been studying denesting radicals. For example: the expression $\sqrt[3]{\sqrt[3]2-1}$ is a radical expression that contains another radical expression, so this radical is nested. Is there a way to express this with radicals that are not (or not as) nested? Writing it in this way is referred to as denesting, and indeed, there is one such way. Ramanujan mysteriously found that $$\sqrt[3]{\sqrt[3]2-1}=\sqrt[3]{\frac 19}-\sqrt[3]{\frac 29}+\sqrt[3]{\frac 49}.$$ I found that this is also equal to $\sqrt{\sqrt[3]{\frac 43}-\sqrt[3]{\frac 13}}$, which does not denest it, but it does write the expression under a radical of a coprime degree, which fascinates me. I have found an abundance of results, one of which fascinates me the most, and is on the constant, $$1-\sqrt[3]{\frac 12}+\sqrt[3]{\frac 14}.$$ This constant is equal to all of the expressions below. Note that the degree of the radicals are, lo and behold, the Fibonacci numbers!
$$\sqrt{\frac 32\bigg(\sqrt[3]2-\frac 1{\sqrt[3]2}\bigg)}$$
$$\sqrt[3]{\frac{3^2}{2^2}\big(\sqrt[3]2-1\big)}$$ $$\sqrt[5]{\frac{3^3}{2^3}\bigg(\frac 3{\sqrt[3]2}-\sqrt[3]2-1\bigg)}$$
$$\sqrt[8]{\frac{3^5}{2^5}\bigg(4-\frac{5}{\sqrt[3]2}\bigg)}$$
$$\sqrt[13]{\frac{3^8}{3^8}\bigg(1+\frac{17}{\sqrt[3]2}-\frac{23}{\sqrt[3]4}\bigg)}$$
and, slightly breaking the pattern,
$$\sqrt[21]{\frac{3^{14}}{2^{14}}\big(41-59\sqrt[3]2+21\sqrt[3]4\big)}$$ and presumably, this list goes on forever (but the numbers start becoming pretty big). So... what on earth is going on here? It appears that for some nth Fibonacci number F_n, this is equal to (for at least most of the time),
$$\sqrt[F_n]{\frac{3^{F_{n-1}}}{2^{F_{n-1}}}\big(a+b\sqrt[3]2+c\sqrt[3]4\big)}$$ for some $\{a, b, c\}\subset \mathbb R$, with a minimal polynomial of $4x^3-12x^2+18x-9$. Can anybody explain these wild affairs? Don't know of any other appropriate tags

Conjecture about minimal number of edge crossings in complete bipartite graphs

I am interested in the status of the conjecture about the minimum number of edge crossings $cr(K_{m,n})$ in a drawing of the complete bipartite graph $K_{m,n}$. The Wikipedia article https://en.wikipedia.org/wiki/Tur%C3%A1n%27s_brick_factory_problem led me to study the original papers of Zarankiewicz (On a problem of P. Turan concerning graphs) from 1954 and of Urbanik (Solution du problème posé par P. Turán) from 1955. I wondered whether someone could tell me whether an asymptotic approach has been successfully attempted (letting $n\to\infty$). If so, I would be very interested in any references for that.

Detecting almost-primes quickly

There are many fast algorithms (deterministic and probabilistic) for detecting primality. Are there any fast algorithms (probabilistic ones allowed) known for detecting whether a number is the product of at most two primes? In this context, can anybody think of a property fulfilled by all or most products of two primes, but by few other numbers? (You can't explicitly use divisor sums or the Moebius function, obviously, as then the game becomes (a) trivial (b) of doubtful computational utility.)

Does the equation $\sigma(\sigma(x^2))=2x\sigma(x)$ have any odd solutions?

This question was posted in MSE in early August 2020. It did garner several upvotes, but did not receive any responses. I have therefore cross-posted it here, hoping that it gets answered. Let $\sigma(x)$ denote the classical sum of divisors of the positive integer x. Here is my question: Does the equation $\sigma(\sigma(x^2))=2x\sigma(x)$ have any odd solutions? MY ATTEMPT I tried searching for solutions to the equation in Sage Cell Server, in the range $1 < x \leq {10}^6$, here is the Pari-GP code: for(x=1, 1000000, if(sigma(sigma(x^2))==2*x*sigma(x),print(x,factor(x)))) Here are the results: 9516[2, 2; 3, 1; 13, 1; 61, 1] 380640[2, 5; 3, 1; 5, 1; 13, 1; 61, 1] Note that both results obtained $x_1 = 9516$ and $x_2 = 380640$ are even. The Pari-GP interpreter of Sage Cell Server crashes as soon as a search limit of ${10}^7$ is specified. CONJECTURE The equation $\sigma(\sigma(x^2)) = 2x\sigma(x)$ does not have any odd solutions. Alas, I have no proof. SOME PARTIAL RESULTS Per Will Jagy's answer (and a subsequent comment by Erick Wong) to the following MSE question, we have the conjectured (sharp?) upper bound $$\frac{\sigma(x^2)}{x\sigma(x)} \leq \prod_{\rho}{\frac{{\rho}^2 + \rho + 1}{{\rho}^2 + \rho}} = \frac{\zeta(2)}{\zeta(3)}.$$ Claim: $\sigma(x^2) \neq p^r$ if prime $p \geq 5$. Suppose to the contrary that the equation $\sigma(\sigma(x^2))=2x\sigma(x)$ has an odd solution, and that $\sigma(x^2) = p^r$ for some prime $p \geq 5$. Then we have $$\frac{\sigma(p^r)}{p^r}=\frac{\sigma(\sigma(x^2))}{\sigma(x^2)}=\frac{2x\sigma(x)}{\sigma(x^2)} \geq \frac{2\zeta(3)}{\zeta(2)} \approx 1.4615259388.$$ But we know that the abundancy index $\sigma(p^r)/p^r$ is bounded above by $$\frac{\sigma(p^r)}{p^r} < \frac{p}{p - 1} \leq \frac{5}{4}.$$ This is a contradiction. Claim: $\sigma(x^2) \neq p^r q^s$ if primes $p \geq 5$ and $q \geq 7$. Suppose to the contrary that the equation $\sigma(\sigma(x^2))=2x\sigma(x)$ has an odd solution, and that $\sigma(x^2) = p^r q^s$ for some primes $p \geq 5$ and $q \geq 7$. Then we have $$\frac{\sigma(p^r)}{p^r}\cdot\frac{\sigma(q^s)}{q^s}=\frac{\sigma(\sigma(x^2))}{\sigma(x^2)}=\frac{2x\sigma(x)}{\sigma(x^2)} \geq \frac{2\zeta(3)}{\zeta(2)} \approx 1.4615259388.$$ But we know that the product of abundancy indices $(\sigma(p^r)/p^r)(\sigma(q^s)/q^s)$ is bounded above by $$\frac{\sigma(p^r)}{p^r}\cdot\frac{\sigma(q^s)}{q^s} < \frac{p}{p - 1}\cdot\frac{q}{q - 1} \leq \frac{5}{4}\cdot\frac{7}{6} = \frac{35}{24} = 1.458\overline{333}.$$ This is a contradiction. Edit (August 27, 2020 - 4:21 PM Manila time) MOTIVATION FOR THE PROBLEM Slowak (1999) proved that an odd perfect number $N = u^t v^2$ (with special prime u satisfying $u \equiv t \equiv 1 \pmod 4$ and $\gcd(u,v)=1$) must be of the form $$\frac{u^t \sigma(u^t)}{2}\cdot{d},$$ where $d > 1$. Dris (2017) showed further that d must have the form $$\frac{D(v^2)}{\sigma(u^{t-1})}=\gcd(v^2,\sigma(v^2))=\frac{\sigma(v^2)}{u^t}=\frac{v^2}{\sigma(u^t)/2},$$ where $D(y)=2y-\sigma(y)$ is the deficiency of y. If the odd perfect number $N = u^t v^2$ is of the form $$\frac{u^t \sigma(u^t)}{2}\cdot{v},$$ then by the results of Slowak and Dris, we have the equations $$\sigma(v^2) = u^t v$$ and $$2v = \sigma(u^t),$$ which led me to my question in this post.

The action of the unitary divisors group on the set of divisors and odd perfect numbers

Let n be a natural number. Let $U_n = \{d \in \mathbb{N}\mid d\mid n \text{ and } \gcd(d,n/d)=1 \}$ be the set of unitary divisors, D_n be the set of divisors and $S_n=\{d \in \mathbb{N}\mid d^2 \mid n\}$ be the set of square divisors of n. The set U_n is a group with $a\oplus b := \frac{ab}{\gcd(a,b)^2}$. It operates on D_n via: $$ u \oplus d := \frac{ud}{\gcd(u,d)^2}$$ The orbits of this operation "seem" to be $$ U_n \oplus d = d \cdot U_{\frac{n}{d^2}} \text{ for each } d \in S_n$$ From this conjecture it follows (also one can prove this directly since both sides are multiplicative and equal on prime powers): $$\sigma(n) = \sum_{d\in S_n} d\sigma^*(\frac{n}{d^2})$$ where σ^* denotes the sum of unitary divisors. Since $\sigma^*(k)$ is divisible by $2^{\omega(k)}$ if k is odd, where $\omega=$ counts the number of distinct prime divisors of k, for an odd perfect number n we get (Let now n be an odd perfect number): $$2n = \sigma(n) = \sum_{d \in S_n} d \sigma^*(\frac{n}{d^2}) = \sum_{d \in S_n} d 2^{\omega(n/d^2)} k_d $$ where $k_d = \frac{\sigma^*(n/d^2)}{2^{\omega(n/d^2)}}$ are natural numbers. Let $\hat{d}$ be the largest square divisor of n. Then: $\omega(n/d^2)\ge \omega(n/\hat{d}^2)$. Hence we get: $$2n = 2^{\omega(n/\hat{d}^2)} \sum_{d \in S_n} d l_d$$ for some natural numbers l_d. If the prime 2 divides not the prime power $2^{\omega(n/\hat{d}^2)}$, we must have $\omega(n/\hat{d}^2)=0$ hence $n=\hat{d}^2$ is a square number, which is in contradiction to Eulers theorem on odd perfect numbers. So the prime 2 must divide the prime power $2^{\omega(n/\hat{d}^2)}$ and we get: $$n = 2^{\omega(n/\hat{d}^2)-1} \sum_{d \in S_n} d l_d$$ with $l_d = \frac{\sigma^*(n/d^2)}{2^{\omega(n/d^2)}}$. Hence the odd perfect number, satisifies: $$n = \sum_{d^2\mid n} d \frac{\sigma^*(n/d^2)}{2^{\omega(n/d^2)}}=:a(n)$$ Hence an odd perfect number satisifies: $$n = a(n)$$ So my idea was to study the function $a(n)$, which is multiplicative on odd numbers, on the right hand side and what properties it has to maybe derive insights into odd perfect numbers. The question is if it ever can happen that an odd number n satisfies: $n=a(n)$? (checked for $n=2k+1$ and $1 \le k \le 10^7$) Edit: Conjecture: For all odd $n \ge 3$ we have $a(n)<n$. This would prove that there exists no odd perfect number. This conjecture could be proved as follows: Since $a(n)$ is

multiplicative, it is enough to show that for an odd prime power p^k we have $$a(p^k) < p^k$$ The values of a at prime powers are not difficult to compute and they are: $$a(p^{2k+1})= \frac{p^{2(k+1)}-1}{2(p-1)}$$ and $$a(p^{2k}) = \frac{p^{2k+1}+p^{k+1}-p^k-1}{2(p-1)}$$ However, I am not very good at proving inequalities, so: If someone has an idea how to prove the following inequalities for odd primes p that would be very nice: $$p^{2k+1} > \frac{p^{2(k+1)}-1}{2(p-1)}, \text{ for all } k \ge 0$$ and $$p^{2k} > \frac{p^{2k+1}+p^{k+1}-p^k-1}{2(p-1)}, \text{ for all } k \ge 1$$ Thanks for your help! The inequalities have been proved here: https://math.stackexchange.com/questions/3807399/two-inequalities-for-proving-that-there-are-no-odd-perfect-numbers

$π(x+y) - π(x) ≤ c·y/\ln(y)$ for some constant c?

(I posted this question on Math SE but it has had no answer for a year now so I would like to ask if anyone here can provide one.) Thinking about the prime number theorem, I wondered whether it is known that there is some constant c such that $π(x+y) ≤ π(x) + c·y/\ln(y)$ for every integers $x,y > 1$. I read that experts believe $π(x+y) ≤ π(x) + π(y)$ fails for some y, since it fails for $y = 3159$ if the k-tuple conjecture holds, but it is just barely false, so I am curious if it is known to be true if the inequality is relaxed by a constant factor. If so, is it also known that $π(x+y) ≤ π(x) + π(y) + c·\!\sqrt{y}·\ln(y)$ for some constant c? I simply do not know how to search for such conjectures, and neither Wikipedia nor Wolfram seem to state any results that would affirm or refute these two conjectures easily, so any references would be appreciated!

Inductively computing Mersenne primes / perfect numbers?

For two sets A,B set $A+B = \{a +b | a \in A,b \in B\}$. Let $(x_n)_{n \in \mathbb{N}}$ be independent variables. Let $\sigma(n)$ be the sum of divisors of n. Set $\hat{\phi}(1) = \{x_1\}$ and then inductively: $$\hat{\phi}(n) = \{x_n\}$$ if $\sigma(k) \neq n$ for all $k \in \mathbb{N}$ and $$\hat{\phi}(n) = \bigcup_{ \sigma(m) = n} \left\{ \sum_{d|m} \hat{\phi}(d) \right\}$$ otherwise. Examples: 1 [x1] 2 [x2] 3 [x1 + x2] 4 [2*x1 + x2] 5 [x5] 6 [x1 + x5] 7 [3*x1 + 2*x2] 8 [4*x1 + 2*x2] 9 [x9] 10 [x10] 11 [x11] 12 [x1 + x11, 3*x1 + 2*x2 + x5] 13 [2*x1 + x2 + x9] 14 [3*x1 + x2 + x9] 15 [7*x1 + 4*x2] 16 [x16] 17 [x17] 18 [x1 + x10 + x2 + x5, x1 + x17] 19 [x19] 20 [x1 + x19] 21 [x21] 22 [x22] 23 [x23] 24 [9*x1 + 5*x2 + x5, x1 + x23, 7*x1 + 4*x2 + x9] 25 [x25] 26 [x26] 27 [x27] 28 [8*x1 + 5*x2 + 2*x5, 6*x1 + x11 + 3*x2 + x5] Conjecture: Let $n=2^{p-1}(2^p-1)$ be an even perfect number. Then there exists a $x \in \hat{\phi}(2n)$, such that, if we plug in 1 for all free variables in x we get: $$ y = x(1,\cdots,1)$$ such that: $$ y+1 = 2^q-1$$ is a Mersenne prime. Furthermore we have: $$N=2^{q-1}(2^q-1)$$ is the next even perfect number after n. I have tested this for $n=6,28,496$. Unfortunately, my naive computation method hits the limit for the next perfect number. So I am asking if somebody can check if the next perfect number satisfies this conjecture or not? It would be nice if you share also your method to check the number. Thanks for your help! Here is some SAGE code I used. And here is some output: n y 6 2 6 6 28 30 496 2 496 126 Edit: Here are the trees corresponding to $2\cdot 6$: [( )] [((12, 6, 1), (12, 6, 2), ____(12, 6, 3) ____(12, 6, 6))] [(/ / / /) ( )] [((3, 2, 1) (3, 2, 2) , (6, 5, 1) (6, 5, 5)), ((12, 11, 1), (12, 11, 11))] And here are the corresponding trees to $2\cdot 28$: [([((56, 28, 1), (56, 28, 2), _____(56, 28, 4) _____(56, 28, 7)_____ _____(56, 28, 14)____ [(/ / / / / / / [((4, 3, 1) ____(4, 3, 3) (7, 4, 1) (7, 4, 2) _____(7, 4, 4) (14, 13, 1) _____(14, 13, 13)_____ [(/ / / / / / / [((3, 2, 1) (3, 2, 2) , (4, 3, 1) ____(4, 3, 3) (13, 9, 1) ____(13, 9, 3) (13, 9, 9) [(/ / / / [((3, 2, 1) (3, 2, 2) , (3, 2, 1) (3, 2, 2) ,) (_____(56, 28, 28)_____) ((56, 28, 1), (56, 28, 2), _____(56, 28, 4) / / / / / /) (/ / (28, 12, 1) (28, 12, 2) ____(28, 12, 3) _____(28, 12, 4) ____(28, 12, 6) _____(28, 12, 12)_____) ((4, 3, 1) ____(4, 3, 3) / / / / / / / / / /) (/ / (3, 2, 1) (3, 2, 2) (4, 3, 1) ____(4, 3, 3) (6, 5, 1) (6, 5, 5) (12, 6, 1) (12, 6, 2) ____(12, 6, 3) ____(12, 6, 6)) ((3, 2, 1) (3, 2, 2) , / / / / / /) ((3, 2, 1) (3, 2, 2) (3, 2, 1) (3, 2, 2) (6, 5, 1) (6, 5, 5)), ( ) _____(56, 28, 7)_____ _____(56, 28, 14)____ _____(56, 28, 28)_____) / / / / / / / / / /) ((7, 4, 1) (7, 4, 2) _____(7, 4, 4) (14, 13, 1) _____(14, 13, 13)_____ (28, 12, 1) (28, 12, 2) ____(28, 12, 3) _____(28, 12, 4) ____(28, 12, 6) _____(28, 12, 12)) ((56, 39, 1), / / / / / / / / / / / / /) ((4, 3, 1) ____(4, 3, 3) (13, 9, 1) ____(13, 9, 3) (13, 9, 9) (3, 2, 1) (3, 2, 2) (4, 3, 1) ____(4, 3, 3) (6, 5, 1) (6, 5, 5) (12, 11, 1) (12, 11, 11)) (/ / / / / /) ((3, 2, 1) (3, 2, 2) , (3, 2, 1) (3, 2, 2) , (3, 2, 1) (3, 2, 2)), ( ) (____(56, 39, 3) _____(56, 39, 13)_____ _____(56, 39, 39)_____) ((56, 39, 1), ____(56, 39, 3) / / / / / / / / / / /) (/ / (3, 2, 1) (3, 2, 2) , (13, 9, 1) ____(13, 9, 3) (13, 9, 9) (39, 18, 1) (39, 18, 2) ____(39, 18, 3) ____(39, 18, 6) (39, 18, 9) _____(39, 18, 18)_____) ((3, 2, 1) (3, 2, 2) , / / / / / / / / / /) ((3, 2, 1) (3, 2, 2) , (3, 2, 1) (3, 2, 2) (6, 5, 1) (6, 5, 5) (18, 10, 1) (18, 10, 2) (18, 10, 5) (18, 10, 10)), ( ]])] _____(56, 39, 13)_____ _____(56, 39, 39)_____)] / / / / / / / / /)] (13, 9, 1) ____(13, 9, 3) (13, 9, 9) (39, 18, 1) (39, 18, 2) ____(39, 18, 3) ____(39, 18, 6) (39, 18, 9) _____(39, 18, 18))] / / / / / / / /)] (3, 2, 1) (3, 2, 2) , (3, 2, 1) (3, 2, 2) (6, 5, 1) (6, 5, 5) (18, 17, 1) (18, 17, 17))] The trees were constructed with the following code: def inductiveGraph(n): from itertools import product ll = [i for i in range(1,n) if sigma(i)==n] #print(ll) if len(ll)==0: return [LabelledOrderedTree([],label=n)] else: phll = [] for m in ll: ml = list(product(*[[LabelledOrderedTree(ph,label=(n,m)) for ph in inductiveGraph(d)] for d in divisors(m)])) #print(n,ml) for x in ml: phll.append(x) return phll print(ascii_art(inductiveGraph(2*28))) Furthermore, plugging in 1 for all variables in $x(1,\cdots,1)$ counts the number of leafs in the tree which corresponds to $x \in \hat{\phi}(2n)$. Related question: Additive number theory, Hilbert spaces and polynomial rings?

What groups should I test my conjecture on?

I have a conjecture that a certain criterion is enough for two groups to be isomorphic. I tested it on all pairs of groups up to size 12, and it worked like a charm. I know, however, that groups are strange and that it is very likely that my conjecture will break for larger groups. I have made myself a python library that handles making groups and seeing they have certain properties/are isomorphic, but I do not know what pairs of groups to test my conjecture on. What groups form a "representative sample" of all groups? What paris of groups would it be absolutely crucial for me to test my hypothesis on? I don't see the need for any answer to be complete, but any ideas for pairs that would be interesting to test on would be appreciated. EDIT: The conjecture is that if two groups have the same count of elements of every order, then they must be isomorphic. I proved this for abelian groups, and am now wondering if it is true in general.

Prove that there are no composite integers $n=am+1$ such that $m \ | \ \phi(n)$

Let $n=am+1$ where $a $ and $m>1$ are positive integers and let p be the least prime divisor of m. Prove that if $a<p$ and $ m \ | \ \phi(n)$ then n is prime. This question is a generalisation of the question at https://math.stackexchange.com/questions/3843195/let-n-apq1-prove-that-if-pq-phin-then-n-is-prime. Here the special case when m is a product of two distinct odd primes has been proven. The case when m is a prime power has also been proven here https://arxiv.org/abs/2005.02327. How do we prove that the proposition holds for an arbitrary positive integer integer $m>1 $? (I have not found any counter - examples). Note that if $n=am+1$ is prime, we have $\phi(n)= n-1=am$. We see that $m \ | \ \phi(n) $. Its the converse of this statement that we want to prove i.e. If $m \ | \ \phi(n) $ then n is prime. If this conjecture is true, then we have the following theorem which is a generalisation (an extension) of Lucas's converse of Fermat's little theorem. $\textbf {Theorem} \ \ 1.$$ \ \ \ $ Let $n=am+1$, where a and $m>1$ are positive integers and let p be the least prime divisor of m with $a<p$. If for each prime q_i dividing m, there exists an integer b_i such that ${b_i}^{n-1}\equiv 1\ (\mathrm{mod}\ n)$ and ${b_i}^{(n-1)/q_i} \not \equiv 1(\mathrm{mod}\ n)$ then n is prime. Proof. $ \ \ \ $ We begin by noting that ${\mathrm{ord}}_nb_i\ |\ n-1$. Let $m={q_1}^{a_1}{q_2}^{a_2}\dots {q_k}^{a_k}$ be the prime power factorization of m. The combination of ${\mathrm{ord}}_nb_i\ |\ n-1$ and ${\mathrm{ord}}_nb_i\ \nmid (n-1)/q_i$ implies ${q_i}^{a_i}\ |\ {\mathrm{ord}}_nb_i$. $ \ \ $${\mathrm{ord}}_nb_i\ |\ \phi (n)$ therefore for each i, ${q_i}^{a_i}\ |\ \phi (n)$ hence $m\ |\ \phi (n)$. Assuming the above conjecture is true, we conclude that n is prime. Taking $a=1$, $m=n-1$ and $p=2$, we obtain Lucas's converse of Fermat's little theorem. Theorem 1 is thus a generalisation (an extension) of Lucas's converse of Fermat's little theorem. This question was originally asked in the Mathematics site, https://math.stackexchange.com/questions/3843281/prove-that-there-are-no-composite-integers-n-am1-such-that-m-phin. On recommendation by the users, it has been asked here.

Updated bounds or references for an old Erdős problem -- coloring the plane with multiple forbidden distances?

Define a graph G_1 where the vertices of G_1 are the points of the plane $\mathbb{R}^2$, and a pair of vertices p, q is connected by an edge if and only if the Euclidean distance $d(p,q) =1$. The Hadwiger-Nelson unit-coloring problem asks for the "chromatic number of the plane": i.e. what is $\chi(G_1)$? The best known bounds are that $5 \le \chi(G_1) \le 7$, with the lower bound improved from 4 to 5 in a breakthrough result by Aubrey de Grey in 2018. Apparently Erdős asked about the following variant. Let $S =\{ d_1, d_2, \dots, d_k \}$ be a set of positive numbers. Define G_S with vertices corresponding to points in the plane, and edges corresponding to pairs of points at any distance d_1, d_2, ..., or d_k. Let $f(k)$ denote the maximum chromatic number $\max \chi(G_S)$ as S ranges over all sets of k positive numbers. Clearly $f(k) \le 7^k$, so $f(k)$ is well defined and is finite for every k. Roughly, how does $f(k)$ grow as $k \to \infty$? According to Soifer (in The Mathematical Coloring Book), Erdős wrote that "it is not hard to see" that $$ \lim_{k \to \infty} \frac{f(k)}{k} \to \infty.$$ As pointed out in the comments, this follows from the fact that a square grid with $\sqrt{n} \times \sqrt{n}$ points only realizes $O \left(n / \sqrt{\log n} \right)$ distinct distances. What are the best known upper and lower bounds on $f(k)$? It was recently shown by Exoo and Ismailescu that $f(2) \ge 6$, but I'm not aware of any nontrivial lower bounds for $f(k)$ even for $k \ge 3$. Any more information for small k would be great, but I'm especially interested in the rate of growth as $k \to \infty$. Erdős apparently asked whether $f(k)$ grows only polynomially fast, and I am wondering whether this is still an open problem.

Profound but not popular mathematical topics and notions

The algebraic Theory of Invariants used to be a hot topic until David Hilbert proved his two theorems about invariants. Then for tens of years, the popularity of the topic went down a long time before it picked up again. Question What are today's mathematical known topics and/or notions that are profound but not popular? Together with an example, could you add an explanation of such a situation? Example from Computer Science -- geometric SIMD (fine grain parallel processing) was a popular and hot topic till the middle of 1980'. Then you hardly hear about it while the idea is as fundamental as always. The explanation is two-folded but very simple. On the one hand, there is some learning and new understanding involved in geometric SIMD processing; one needs to acquire new habits, new reflexes. On the other hand, the technology progress was such that people were satisfied with the results obtained without bothering with the SIMD ways. (Underneath, the new traditional computer architecture is not that traditional -- these days, it incorporates quite a bit of parallelity). We see that the geometric SIMD is not popular for the wrong reasons, and a lot of potentials is

wasted.

A conjectured upper bound for the mean value of prime divisors inside prime gaps

In 1969 C.A. Grimm stated this interesting conjecture: the prime gap $\,G_n=\{x\in N:p_n\lt x\lt p_{n+1}\}\,$ contains at least $\,\#G_n=(p_{n+1}-p_n)-1=g_n-1\,$ distinct prime divisors, that is if $\,V(n)=(p_n+1)(p_n+2)...(p_{n+1}-1)$ $$\omega\,[V(n)]\ge g_n-1$$ Let's define the following additive arithmetic function: $$\sigma_p(n)=\sum_{k=1}^r p_k\;\;\;\;\;(\,n=\prod_{k=1}^r p_k^{a_k}\,)$$ Well, I have made some computations in order to conjecture a possible estimate for $\,\sigma_p(V(n))$. The following graph reports the values ($x10^6$) of $\,\sigma_p(V(n))-p_n\,$ till $\,n=10^5$: A possible estimate should be $$\sigma_p(V(n))=2n\,(\log n)^{3/2}+O(n\log n)$$ But under Cramér's conjecture $\,g_n=p_{n+1}-p_n=O((\log p_n)^2)$, therefore we can deduce the following upper bound for the mean value of prime divisors inside the gap $\,g_n$: $$\frac {\sigma_p(V(n))} {\omega\,[V(n)]}\lt\frac {2n\sqrt {\log n}} {\log n+2\log {\log n}}\lt\frac {2n} {\sqrt {\log n}}$$ Notice that the max prime divisor inside the gap is less than $$\frac {p_{n+1}} 2\sim\frac {n\log n+g_n} 2\sim\frac {n\log n+(\log n)^2} 2\sim\frac {\log n\,(n+\log n)} 2$$ I ask your opinions and suggestions about the above arguments. Many thanks.

How to put a monetary incentive on an open research problem?

Since the old days, many famous mathematicians have been attaching monetary rewards to problems. I would like to put monetary bounties on some research mathematics problems. Some of those problems might be solved or partially solved by a hard-working college graduate in pure math. The ideal platform to put these questions would be a website like MathOverflow: high visibility, acceptable ranking algorithm, and little distractions (Ads). However, I have yet to find a single forum for posting these kind of questions, let alone being "ideal". I am not sure if we could attach a monetary incentive in the body of the question here on this site. I could also hire a research assistant but I am not sure if I could attract a high quality one as I am not a tenure-track faculty at a renowned institute. Another alternative will be freelancing websites. However, no one put research math questions there: those sites are full of coding problems and homework problems. And of course, we could publish an advertisement just like what have done by those famous mathematicians. However, with little reputation, we are unlikely to attract enough attention. What resources do we have for posting the open research problems?

Open problems in matroid theory

I read Oxley's book on matroid theory and found the theory fascinating. At the end, Oxley stated some open problems and conjectures in matroid theory. Are there any modern lists about such problems? Are there more open conjectures in matroid theory?

How small the radical of $xyz(x+y+z)$ can be infinitely?

This is an open problem. Let x,y,z be coprime integers (not necessarily pairwise coprime) and no proper subset sum of $\{x,y,z,-(x+y+z)\}$ is zero. For a quadruple $(x,y,z,-(x+y+z))$ define the quality
$$q(x,y,z,-(x+y+z))=\frac{\log{(\max(|x|,|y|,|z|,|x+y+z|))}}{\log(rad(xyz(x+y+z))}$$ where rad is the radical. We have quality $q= 3+o(1)$ given by $$x=1, y=3 (t - 1) t, z=(t - 1)^3, -(x+y+z)=-t^3$$ and at integers set $t=2^{large}$. Can we get quality $3+C$ infinitely often for positive C?

Walking to infinity on the primes: The prime-spiral moat problem

It is an unsolved problem to decide if it is possible to "walk to infinity" from the origin with bounded-length steps, each touching a Gaussian prime as a stepping stone. The paper by Ellen Gethner, Stan Wagon, and Brian Wick, "A Stroll through the Gaussian Primes" (American Mathematical Monthly, 105: 327-337 (1998)) discusses this Gaussian moat problem and proves that steps of length $< \sqrt{26}$ are insufficient. Their result was improved to $\sqrt{36}$ in 2005. My question is: Is the analogous question easier for the prime spiral (a.k.a. Ulam spiral)-Can one walk to infinity using bounded-length steps touching only the spiral coordinates of primes? What little I know of prime gaps suggest that should be easier to walk to infinity. For example, the first gap of 500 does not occur until about 10^{12} (more precisely, 499 and 303,371,455,241). I ask this primarily out of curiosity, and have tagged it 'recreational.' Edit1. In light of Gjergji's remarks below, I have tagged this as an open problem. Edit2. Just for fun, I computed which primes are reachable on a small portion of the spiral, for step distances $d \le 3$ (left below) and $d \le 4$ (right below); red=reached, blue=not reached. The former does not reach 83, the 23rd prime blue dot barely discernable at spiral coordinates (5,-3); the latter does not reach 5087, the 680th prime blue dot at spiral coordinates (36,10).

Dense sets in $\Bbb{R}^2$ with rational distance

We call a subset $S\subset \Bbb{R}^2$ rationally distanced if all $s_1,s_2 \in S$ have rational Euclidean distance. The Erdos-Ulam conjecture asks if there is a dense subset of $\Bbb{R}^2$ which is rationally distanced. Inspired by this, I came up with the following toy problem. A subset $X \subset \Bbb{R}^2$ is good if there exists a rationally distanced $S \subset \Bbb{R}^2\setminus \overline{X}$ such that each $x\in X$ is a limit point of S. I have three questions: Is $[0,1]\times \{0\}$ good? If $[0,1] \times \{0\} $ is not good, does this imply a negative solution to the Erdos-Ulam conjecture? (i.e. can we show that no rationally distanced subset S of $\Bbb{R}^2$ can intersect all possible line segments in $\Bbb{R}^2$) Is there an infinite good set that is not a subset of a straight line? (to avoid trivial examples like $\{n+\sqrt{2}:n\in \Bbb{Z}\}\times \{0\}$ for which $\Bbb{Q}\times\{0\}$ is a solution) Edit: Question 2 is straight-forward. Obviously, for S to intersect each of the line segments $\{[0,1]\times \{\alpha\}:\alpha \in \Bbb{R}\}$, we must have S be uncountable. Originally I saw this much, but didn't know how to deal with the distance function not being injective. For S to be dense in $\Bbb{R}^2$, there must distinct $s_1,s_2,s_3 \in S$ which are not collinear. We then have that the map $\phi:x \mapsto (|x-s_1|,|x-s_2|,|x-s_3|)$ is a injection from $\Bbb{R}^2$ to $\Bbb{R}^3$. The uncountability of S then immediately gives that $\phi(S) \not\subseteq \Bbb{Q}^3$, hence there exists some $i \in \{1,2,3\}, s^* \in S$ such that $|s_i-s^*|$ is irrational, making S not rationally distanced. Edit 2: Wojowu pointed out that since there are rationally distanced subsets of the unit circle, we can get infinite good sets that are not subsets of a line. So Question 3 as stated here is resolved in the positive. I'm still interested to see other constructions, but I will ask about that in a future post, after I've collected my thoughts.

What heuristic evidence is there concerning the unboundedness or boundedness of Mordell-Weil ranks of elliptic curves over $\Bbb Q$?

Some experts have a hunch that for any nonnegative integer r there are infinitely many elliptic curves over $\Bbb Q$ with Mordell-Weil rank at least r. The best empirical evidence for this hunch can be found in Andrej Dujella's tables here and here, the strongest of this evidence being provided by Elkies using constructions involving K3 surfaces. The only heuristic evidence I know of supporting this hunch is the results of Tate and Shafarevich (strengthened by Ulmer) that the Mordell-Weil ranks of elliptic curves over the a fixed function field $\Bbb F_q(t)$ can be arbitrarily large. What other heuristic evidence (if any) is there that the ranks of elliptic curves over $\Bbb Q$ should be unbounded? Seeing as how some experts do no believe this conjecture, I'd also accept answer to the companion question: What heuristic evidence (if any) is there that the ranks of elliptic curves over $\Bbb Q$ should be uniformly bounded?

Is it a reasonable way to write a research article assuming truth of a conjecture?

I have found a conjecture in a research article (published in a good journal) on number theory, which is not well known but very reasonable. Let me be clear that, there is no counter-example that vote down the conjecture, rather, its trueness has been proved in some special situation so far. I need this conjecture to develop a tool in order to write a research article. Unfortunately, I am unable to prove the conjecture as of now. Maybe others can prove it after some time. My question: Is it a reasonable way to write a research article assuming truth of the conjecture?

Status of a conjecture of Hirzebruch

I was reading a paper from 1994 which claimed that the following statement was a conjecture of Hirzerbruch: If a complex surface X is homeomorphic to either $S^2 \times S^2$ or $\mathbb{C}P^2 \# \overline{\mathbb{C}P^2}$ then it is biholomorphic to one of the Hirzerbruch surfaces. I would like to know if this conjecture has been resolved or what the current status about it. Also, I would like to know the state of the art about the variant of the conjecture in which "homeomorphic" is replaced by "diffeomorphic": If a complex surface X is diffeomorphic to either $S^2 \times S^2$ or $\mathbb{C}P^2 \# \overline{\mathbb{C}P^2}$ then is it biholomorphic to one of the Hirzerbruch surfaces? If this has been proved, what is a reference?

Projective Plane of Order 12

I asked this question on the new Theoretical Computer Science "overflow" site, and commenters suggested I ask it here. That question is here, and it contains additional links, which I doubt I can embed here because I don't have enough reputation. Anyway, here goes: Objective: Settle the conjecture that there is no projective plane of order 12. In 1989, using computer search on a Cray, Lam proved that no projective plane of order 10 exists. Now that God's Number for Rubik's Cube has been determined after just a few weeks of massive brute force search (plus clever math of symmetry), it seems to me that this longstanding open problem might be within reach. I'm hoping this question can serve as a sanity check. The Cube was solved by reducing the total problem size to "only" 2,217,093,120 distinct tests, which could be run in parallel. Questions: There have been special cases of nonexistence shown (again, by computer search). Does anyone know, if we remove those and exhaustively (cleverly?) search the rest, if the problem size is on the order of the Cube search? (Maybe too much to hope for that someone knows this....) Any partial information in this vein?

Cramer-Castillon problem like

Special case of Golden ratio as a property of conic section (is it known?) as follows: Let ABC be arbitrary triangle and DEF is the its tangential triangle. Let CF meets AB at G and BE meets AC at H, let GH meets the circumcircle at I. A line through I and parallel to EF meets AB, AC at J, K then $$\frac{JK}{JI}=\frac{\sqrt{5}+1}{2}$$ Open problem: Cramer-Castillon problem being very difficult problem. Related to the Cramer-Castillon problem configuration, I posed a problem as follows: Let ABC be arbitrary triangle and let three collinear points E', F', D' such that $\frac{E'F'}{E'D'}=k$ where k is positive real number. How can construct points D in the circumcircle of $ \triangle ABC$, E in AB, F in AC such that D, E, F are collinear and $\frac{EF}{ED}=k$?

Infinite dimensional Newlander-Nirenberg theorem

The Newlander-Nirenberg theorem states that an almost complex structure is integrable if and only if the Nijenhuis tensor vanishes. I heard that this statement is not true in infinite dimensions, since for example the Loop space of a Riemannian 3-manifold is counterexample. (In fact, I think NN fails for Fréchet manifolds in general(?)) So my question is: Is the Newlander Nirenberg theorem valid for Banach- or Hilbertmanifolds? If not, is it possible to weaken the statement (or some conditions) such that it remains true for some class of infinite dimensional manifolds? EDIT: Added the tag "open-problem", since NN for Hilbertmanifolds seems to be an open problem.

Factoring integers of the form $n=p q^2$ using elliptic curves

We got argument and strong experimental support that integers of the form $n=p q^2$ can be factored using elliptic curves easier than general integers Q1 Is this known? Added This is known since at least 2002: Factoring N = p q^2 with the Elliptic Curve Method Q3 Can the method be improved for general integers? Assume E is elliptic curve modulo n with known point P of the order of P over $\mathbb{F}_p$ is $\rho = S U$ where S is B_1 smooth. We can find the factor p working over the curve modulo n in time $O(B_1 + \sqrt{U})$ and constant memory. It is an open problem if this can be generalized to arbitrary n. Stage 1: This is the first stage of the elliptic curve factoring algorithm. Set $Q=P$ and for primes r, $r \le B_1$ let $Q=r^{\log_r{n}} Q$. If we reach the point at infinity modulo p we are done and the algorithm stops with factor p. Stage 2: This is based on the birthday paradox and Pollard's rho algorithm for discrete logarithms in groups. Let $\mathrm{kronecker}(a,n)$ denote the kronecker symbol and for a point a on an elliptic curve $X(a)$ denote the X coordinate of a. For points a,b on E define the function $f(a,g)$: If $\mathrm{kronecker}(X(a),n)=1,f(a,g)=2 a + 5 g$, else $f(a,g)=3 a + g$. For Q from stage 1, set $a=Q,b=Q,g=Q$. For n from 1 to B_2 set $a=f(a,g),b=f(b,g),b=f(b,g)$. If $\gcd(X(a)-X(b),n) \bmod n>1$ return the factor. Stage 2 finds multiple of $U Q$ in time B_2 while $U \sim B_2^2$. Since the kronecker symbol is multiplicative, we have $\mathrm{kronecker}(a,n)=\mathrm{kronecker}(a,p)$ for a coprime to n. Iterates of $f^k(a,g)$ are deterministic random walk modulo p, so $f^N(a,g)=f^{2N}(a,g)$ happens for $N = O(\sqrt{U}) \sim B_2$.

Is the unit-stick number of a knot equal to its stick number?

Define the unit-stick number $\sigma_1(K)$ of a knot K to be the fewest unit-length sticks that can realize K. Clearly $\sigma_1(K)$ is at least the stick number $\sigma(K)$. It is known that the trefoil knot K_{3_1} has stick number 6; see the image below. I believe, although I don't have a formal proof, that $\sigma_1(K_{3_1})=6$: the trefoil also has unit-stick number 6. (Wikipedia image by Wiebew. The sticks are not all the same length.) Q. Is $\sigma_1(K) = \sigma(K)$ for every knot K? If not, what is a knot for which it can be proved that the unit-stick number is strictly greater than the stick number, $\sigma_1(K) > \sigma(K)$? Related: Which knots' stick numbers are twice their crossing numbers?. Update. User @aorq's comment shows that my "unit-stick number" has been studied under the name "equilateral stick number": Rawdon, Eric J., and Robert G. Scharein. "Upper bounds for equilateral stick numbers." Contemporary Mathematics 304 (2002): 55-76. These authors proved that indeed the trefoil has equilateral stick number 6. They identify the 8_{19} knot as possibly one whose equilateral stick number is greater than its stick number. So, about 20 years ago, it appears that the question I posed was an open problem.

Must Mersenne numbers be divisible by arbitrary large primes with exponent one?

Let M_n denote the Mersenne numbers $M_n=2^n-1$. As n varies, must M_n be divisible by arbitrary large prime p with exponent one, i.e. $p \mid M_n, p^2 \nmid M_n$? In other words, must the exponential diophantine equation $2^n-1 = A x^2 y^3$ for constant A has only finitely many solutions (n,x,y) and $n >1$? Related question is this. Also related question that might show there are infinitely many non-Wieferich primes is here. Looking for unconditional results, abc easily implies it. Added The paper Remarks on Exponential Congruences and Powerful Numbers P. RIBENBOIM on p7. (M') There exist infinitely many Mersenne numbers which are not powerful. (M') implies B_2 implies infinitely many non-Wieferich primes. One easy way to construct infinitely many non-powerful Mersenne numbers is to observe that 3 divides M_{6n+2} with exponent one, so M_{6n+2} is not powerful. Doesn't this approach give infinitely many non-Wieferich primes?

Conjectures or Results?

There is a paper (not accepted for publication yet) that contains several conjectures. Some of these conjectures were proven recently. The referee of the original paper requires to substitute the proven "Conjectures" with the "Results". However, there are several papers that cite these conjectures, so I feel it would be wrong to rename them. What is the best (or standard) way to indicate in the original paper that the conjectures were proven in the subsequent papers? Are there any good examples of doing that?

Simple example of Hammerstein integral equation

I'm currently reading this paper (and working on a similar one). The main goal is to study the Hammerstein integral equation (in $\mathcal{C}(I,E)$: $$x(t) = \int_{0}^{t} K(t,s)f\big(s,x(s)\big)ds,\quad t\in I;$$ where $I=[0,1]$, $K $ is a scalar kernel, E a Banach space and $f:I \times E \rightarrow E$ is a given function. Let's say that in my hypothesis, I need: H_1. There exist $a:I \rightarrow (0,+\infty)$ with $a(.)\in L^{\infty}(I)$ and $b:[0,+\infty) \rightarrow(0,+\infty)$ a nondecreasing function such that $\|f(s, x)\| \leq a(s) b\big(\|x\|\big)$ for a.e. $s \in I$ and $x\in E$, H_2. there exists at least one solution $r \in \mathcal{C}\big(I,(0, \infty)\big)$ to the inequality $$ b\left(\|r\|_{\infty}\right) \int_{0}^{t} \left |K(t, s) \right |a(s) d s \leq r(t), \quad t \in I$$ where $\|.\|_{\infty}$ is the sup norm in $\mathcal{C}\big(I,(0, \infty)\big)$. But I'm wondering if those are reasonable assumptions. I'm looking for an example of the Hammerstein integral equation with the hypothesis (H_1) and (H_2), take $\color{blue}{E=\mathbb{R}}$ for simplification.

Minimal surface in a ball

Assume a minimal surface Σ has boundary on the unit sphere in the Euclidean space and r is the distance from Σ to the center of the ball. Is it true that $$\mathop{\rm area} \Sigma\ge \pi\cdot(1-r^2).$$ Comments: The problem is solved in all dimensions and codimension, see "Area bounds for minimal..." by Brendle and Hung in 2016. (Thanks Rbega for the ref.) If $r=0$, the statement follows directly from the monotonicity formula. If Σ is topological disc the answer is YES, see answer of Oleg Eroshkin below. The general question is formulated as a conjecture in 1975 --- see comment of Ian Agol. There is an analog in all dimension and codimension for area minimizing surfaces, see Alexander, H.; Hoffman, D.; Osserman, R. Area estimates for submanifolds of Euclidean space. 1974.

Inscribed square and convexity

Let $b(X)$ be the boundary of any X subset of the plane. Does there exist A,B convex compact sets of the plane, such that $C:=A\setminus B$ is simply connected and not empty, and such that there is no square inscribed in $b(C)$ that has a vertex in $b(C)\setminus B$? If the answer is no, this would kind of mean that the Toeplitz conjecture is kind of linked to convexity (one of the first intersting resolved cases was the case of the boundary of a convex) If the answer is yes... then it suggests a "fractal" way to built some counterexample. Do not hesitate to say your "prognosis" in the comments, even if it is not argued so far, I have absolutally no intuition myself about the pronostic (I would say it must be "NO" but I would be influenced by the fact that according to me, if it is "YES", then there is a counterexample not far, and this would have been found - but I might as well underevaluate the difficulty of "YES=> counterexample" ...)

The 4th Lemoine circle

The first and second Lemoine circles are well-known to geometers. According to this article the third Lemoine circle has been first discovered by Jean-Pierre Ehrmann in 2002. It is worth noting that the centres of these circles belong to a line that is going through the Lemoine point and the circumcenter of the triangle. I would like to present the construction of another circle, which I believe might be called the 4th Lemoine circle. The idea behind its construction is slightly similar to that proposed by Ehrmann: Symmedians AA', BB', CC' intersect each other at the point M (the Lemoine point of the triangle ABC). The circumcircle of the triangle A'B'C' was drawn (also known as the 'symmedial circle'). A'', B'', C'' are the first intersection points of the symmedians with the symmedial circle. Finally, the circumcircles of the triangles A''B''M, B''C''M, A''C''M always intersect the sides of the original triangle ABC at six points, that are conclycic. Theorem illustration As far as I can tell the point O (the center of our six point circle) is not included into the C.Kimberling's Encyclopedia, so it must be unknown or uncatalogued. O belongs to the line that contains the centres of the first three Lemoine circles, so by my reckoning, the dotted red circle that is shown in the picture above perfectly qualifies for being called the 4th Lemoine circle. Could you please give a synthetic proof of this theorem ? Geogebra dynamic sketch.

Planar subsets with many pairs of points on distance 1

Let X be a subset of $\mathbb R^2$ consisting of n distinct points. Let $d_1(X)$ be the number of pairs of points of X on distance 1 from each other. Define $$d_1(n)=\sup_{X\subset \mathbb R^2|, |X|=n}d_1(X).$$ In particular $d_1(1)=0$, $d_1(2)=1$, $d_1(3)=3$, $d_1(4)=5$, etc. Question. I wonder what is known about the asymptotic behaviour of $d_1(n)$ and about its upper bound? It should be at least $n\log(n)$ as the following example shows: Example. It is easy to see that $d_1(2^d)\ge d2^d$, indeed, one can take the set Y consisting of d unit vectors and then take 2^Y consisting of sums of vectors over all 2^d subsets of Y. Then for generic Y we have $|2^Y|=2^d$ and $d_1(2^Y)=d2^d$. By fiddling a bit with Y one can increase $d_1(2^Y)$.

Heuristics for the very little torsion in the cohomology of Shimura variety

Consider the following statement which is a part of Conjecture 1.3 in the paper titled "The asymptotic growth of torsion homology for arithmetic groups" authored by N. Bergeron and A. Venkatesh. Let G be a $\mathbb{Q}$-semisimple group of zero defect(includes the Shimura variety case) and let $K \subset G(\mathbb{R})$ be a maximal compact subgroup and $\Gamma \subset G(\mathbb{Q})$ be a congruence subgroup. Denote the locally symmetric space $\Gamma \backslash G(\mathbb{R})/K$ by X_{Γ}. Let Γ_N denote the descending family of congruence subgroups such that $\cap \Gamma_N = \lbrace 1 \rbrace$. Then $$ \lim_{N \to \infty} \frac{\log |\mathrm{H}^i(X_{\Gamma_N}, \mathbb{Z})_{tors}|}{[\Gamma : \Gamma_N]} = 0. $$ I was wondering what are heuristics for this conjecture? What are the evidence available for this conjecture? Is something known in the case of Shimura varieties? Any help of reference is appreciated. Thank you.

The 4th vertex of a triangle?

I was immensely surprised and amused by the idea of the fourth side of a triangle that was introduced by B.F.Sherman in 1993. 'Sherman's Fourth Side of a Triangle' by Paul Yiu is available here. Naturally a question arises whether it is possible to determine the '4th vertex' of a triangle in a somewhat similar way? Basically a vertex of the given triangle can be described as a point that is lying on its circumcircle. Then the middle point of the segment connecting this point to the Orthocenter must belong to the nine point circle of the triangle. (This holds true for any point that is lying on the circumcircle.) Finally it appears that we should just add another equation somehow linking our 'vertex' to the inscribed circle. In other words, there might exist some triangle center on the circumcircle that is also satisfying a certain condition related to the inscribed circle, so that eventually this point can be called the fourth vertex of the triangle. Luckily I found in my files a construction of a triangle center X that in a sense satisfies these conditions: It belongs to the circumcircle of ABC The midpoint of the segment XX(4) belongs to the nine point circle. The constriction of X primarily relies on the Incenter of the triangle (i.e. the inscribed circle) Last but not least, this point X is not included in Kimberling's encyclopaedia: A',B',C' is the circumcevian triangle with respect to the Incenter I. Lines AB and A'B' intersect at point C'', points B'', A'' are defined cyclically. Circumcircles for the triangles IRA, IRB, IRC were drawn. These 3 circles intersect the circumcircle at the points A''', B''', C'''. Finally A''A''',B''B''',C''C''' always cross each other at some point X that conveniently belongs to the circumcircle of the original triangle ABC. Geogebra dynamic sketch. It is highly speculative to call our point X the fourth vertex of a triangle, of course. Presumably this attribution will be outright dismissed or proven wrong. However I assume that perhaps a better fit for the 4th vertex of a triangle can be found? What would its construction be?

Lemoine-Lozada circles

I made some rookie attempt to define the 4th Lemoine circle recently. The alternative name for this circle was suggested yesterday. Further investigation revealed a family of circles associated with the Brocard axis. Supposedly the name of Ehrmann-Lozada circles (or Lemoine-Lozada circles) can be safely attached to them. Specifically, it appears that for each Lozada circle it is possible to construct at least one circle of the Lemoine type, with its center on the line that is going through the Symmedian point and the circumcenter of the triangle. step 1: Let A'B'C' be the midheight triangle of ABC and let BA and CA be the orthogonal projections of B' and C' on BC, respectively. Build AB, CB, AC and BC similarly. These last six points lie on a circle with center X(9729). The circle is called the 1st Lozada circle. (César Lozada, March 17, 2016) step 2: Circumcircles of the triangles BcAcX(6), AbCbX(6), BaCaX(6) cut the sides of the original triangle at six points, that define the 1st Ehrmann-Lozada circle. Its center O_1 is not in the ETC. Ehrmann-Lozada circles can be constructed in the similar manner for each(?) of the ten remaining Lozada circles:
https://www.geogebra.org/geometry/pg9mrmzx 2 new circles of the Lemoine type
https://geogebra.org/geometry/uqnpqjeh 2 new circles of the Lemoine type
https://www.geogebra.org/geometry/t4jpn9dp only 1 new circle of the Lemoine type ... 11. https://www.geogebra.org/m/kppjdcny gives us only 1 new circle of the Lemoine type... More links will be added soon. None of these points O_i is included in Clark Kimberling's encyclopaedia. Finding a strict proof of existence of these new circles is the main question here. Bit I am also interested in what makes Lozada points/circles so special? (Taylor point belongs to the Brocards Axis as well, but for some reason it is impossible to construct an Ehrmann-Taylor circle in the same way!) Are these Ehrmann-Lozada circles also Tucker circles?

A special case of Frankl's conjecture. A question about known results

Let's recall a Frankl's conjecture. Consider a finite family of finite sets $\mathcal{F}$, such for every pair of sets $A\in \mathcal{F}$ and $B\in\mathcal{F}$, we have $A\cup B\in\mathcal{F}$(the family $\mathcal{F}$ is said to be union closed). The conjecture says that there is an element $a\in \bigcup_{A\in\mathcal{F}}A$, so that $a\in A$ for at least $\frac{|\mathcal{F}|}{2}$ sets A. Now, let's take a set $U=\{1,2,...,n\}$ and an union closed family $\mathcal{F}'\subseteq\mathcal{P}(U)$, where $\{U,\emptyset\}\cup\mathcal{P}_{n-1}(U)\subseteq\mathcal{F}'$. Is it known whether this case is solved? I would like to see a proof of this specific case. I was trying to figure it out myself by considering an induction in respect to $|U|$, but i failed. Thank you for any help or hint.

On improving the upper bound $I(m^2) \leq \frac{2p}{p+1}$, if $p^k m^2$ is an odd perfect number with special prime p

(Preamble: This question is an offshoot of this answer to an MSE question with the same title.) Denote the classical sum of the divisors of the positive integer x by $\sigma(x)=\sigma_1(x)$ and the abundancy index of x by $I(x)=\sigma(x)/x$. Let $p^k m^2$ be an odd perfect number with special prime p satisfying $p \equiv k \equiv 1 \pmod 4$ and $\gcd(p,m)=1$. Since we have $$I(m^2) \leq \dfrac{2p}{p+1}$$ and because $p^k m^2$ is perfect, then we have $$I(p^k)I(m^2) = I(p^k m^2) = 2$$ where we have used the fact that the abundancy index function is multiplicative. Hence, we obtain (via iteration) $$\text{First iteration: } I(m^2) \leq I(p^k)I(m^2)\cdot\dfrac{p}{p+1} \leq 2I(p^k)\cdot\dfrac{p^2}{(p+1)^2}$$ $$\text{Second iteration: } I(m^2) \leq \bigg(I(p^k)\bigg)^2 {I(m^2)} \cdot\dfrac{p^2}{(p+1)^2} \leq 2\bigg(I(p^k)\bigg)^2 \cdot\dfrac{p^3}{(p+1)^3}$$ $$\ldots$$ $$\ldots$$ $$\ldots$$ by recursively replacing 2 with $I(p^k)I(m^2)$ and then bounding $I(m^2)$ from above by $2p/(p+1)$. Note that, at the n^{th} iteration, we have the inequality $$I(m^2) \leq 2\bigg(I(p^k)\bigg)^n \cdot \dfrac{p^{n+1}}{(p+1)^{n+1}}.$$ Repeating the process ad infinitum, we get $$I(m^2) \leq \lim_{n \rightarrow \infty}{2\bigg(I(p^k)\bigg)^n \cdot \dfrac{p^{n+1}}{(p+1)^{n+1}}} = \lim_{n \rightarrow \infty}{\dfrac{2\bigg(I(p^k)\bigg)^n}{\dfrac{(p+1)^{n+1}}{p^{n+1}}}}$$ $$= \dfrac{2p}{p+1}\cdot\lim_{n \rightarrow \infty}{\dfrac{\bigg(I(p^k)\bigg)^n}{\bigg(I(p)\bigg)^n}},$$ where the limit is of the indeterminate form $$\dfrac{+\infty}{+\infty}.$$ Hence, we may apply L'Hôpital's rule, by considering $$h(p) = \dfrac{\bigg(I(p^k)\bigg)^n}{\bigg(I(p)\bigg)^n}$$ as a function of p. (Also, note that there is "currently no L'Hôpital's rule for multiple variable limits". The closest thing that I could find on arXiv is this preprint by Gary R. Lawlor.) I tried working on applying L'Hôpital's rule to $h(p)$, by asking for help from WolframAlpha, however the

computations are a mess. Here is my inquiry: QUESTION: Is it possible to simplify the computations, via say, some recursive rule that I do not know about?

A counterexample to a conjecture of Lawson

Yau quotes Lawson as having formulated the following conjecture [1]: Let M be an embedded minimal surface in $\mathbf{S}^3$. Prove that the two domains in $\mathbf{S}^3$ divided by M have equal volume. This is easily seen to hold for the simplest two minimal surfaces in $\mathbf{S}^3$, namely the equatorial spheres and the Clifford tori; it was also known at the time that the analogous statement fails in higher-dimensional spheres. (Whether it holds for the Lawson surfaces in $\mathbf{S}^3$ I do not know.) Question. I remember reading a statement claiming that some surface had been found to contradict the proposed statement. Does somebody know which surface this is? Unfortunately I cannot seem to remember where I read this, and online searches are obscured by Lawson's other, more prominent conjecture. [1] Shing-Tung Yau. Problem section. Seminar on Differential Geometry. 102 (1982) pp.669-706.

Base locus of divisors on blowings up of the projective space

Let X be the blowing-up of $\mathbb{P}^n$ in r points in general position. Let $\{H,E_1,...,E_r\}$ be the standard basis of $Pic(X)$. Further let $D=dH-\sum m_j E_j$, be an effective divisor, with $m_j \in \mathbb{Z}$. Is it true that if $m_1\geq 0$ then $E_1 \not\subseteq Bs(|D|)$? If we suppose all the m_i's are non negative, this corresponds to say that $dim |dH-m_1E_i...-m_rE_r|>dim |dH-(m_1+1)E_1-...-m_rE_r|$. In other words this means that if we consider all the hypersurfaces of $\mathbb{P}^n$ of degree d passing through r general points $\{p_1,...,p_r\}$ with multiplicities $m_1,...,m_r$, then they do not all pass through p_1 with multiplicity m_1+1. My intution brings me to say this is obvious but I cannot prove it. In fact everything is trivial for nonspecial linear systems, but, a priori, special linear systems may be a problem. Note that the generality of the points is necessary: for example you can simply take $\mathbb{P}^2$ blown up in 3 collinear points and note that $E_1 \subseteq Bs(|H-E_2-E_3|)$.

An open triangle problem in plane geometry

Some years ago, I asked some 'famous' people in an advanced Plane Geometry forum about the following: Let ABC be arbitrary triangle, how can one construct a point P in the plane such that P is the circumcenter of the cevian triangle of P with respect to $ABC?$ The answer was negative, even in the sense of calculations by a Computer (can't construct by rule and compass, even can not calculations by computer). My conjecture: Let ABC be arbitrary triangle, then there exist a point P such that P is the circumcenter of the cevian triangle of P with respect to ABC. Question: How can prove conjecture and how construct this point?

Distinct exponents in the factorization of the factorial, a problem of Erdős

In the 1982 paper below, Paul Erdős proved that if $h(n)$ is the number of distinct exponents in the prime factorization of $n!$ then $$c_1\Big(\frac{n}{\log n}\Big)^{1/2} < h(n) < c_2\Big(\frac{n}{\log n}\Big)^{1/2}$$ for all sufficiently large n, where c_1, c_2 are positive constants. Then he said that "there is no doubt" that $$h(n) = (c + o(1))\Big(\frac{n}{\log n}\Big)^{1/2}$$ as n goes to infinity, for some positive constant c, but that "we do not know enough about the difference of consecutive primes" to conclude so. I wonder if now, after 40 years, "we" know enough to prove Erdős conjecture (?) P. Erdős, Miscellaneous problems in number theory, Congressus Numerantium 34 (1982), 25-45. https://users.renyi.hu/~p_erdos/1982-08.pdf

Special values of Artin L-functions

This question might be naive and might carry the heuristic that we are living in the best possible world a little too far. If so, I appreciate being told so. Background: Stark's conjecture interprets the leading coefficients of Artin L-functions around $s=0$ as certain regulators. Let F/K be a Galois extension of number fields and ρ an Artin representation of the absolute Galois group of K factoring through F. Let $L(F/K,\rho,s)$ be the Artin L-function attached to ρ and let $c(\rho)$ be the leading coefficient of its Taylor expansion around $s=0$. Then Tate's formulation of Stark's conjecture does the intuitive thing and "picks out the ρ-isotypical bit" of the units $\mathcal{O}_F^\times$ and measures its volume in a suitable sense. But there are various problems with this intuition and it doesn't quite work the way one would like to (see below). The result is that one only gets a complex number Reg(ρ) that is well defined up to a rational multiple. The conjecture is that this complex number accounts for the transcendental part of $c(\rho)$, more precisely that Reg$(\rho)/c(\rho)$ is algebraic and that Galois acts on this quotient through its action on the Artin characters. There is a different circle of conjectures, due to Beilinson, Bloch, Burns, Flach, Fontaine, Kato and Perrin-Riou, subsumed under the bracket of "Tamagawa number conjectures", which gives exact predictions for special values of much more general motivic L-functions. Some of these conjectures work up to units, but some of them give actual

numbers. The regulators involved are rather more complicated motivic things and, being a hands-on person, I find it difficult to discern the arithmetic in them (I know, this is embarassing to admit for someone who works on Galois module structures). Question: Does anyone know of an explication of the Tamagawa number conjectures in the setting of Artin L-functions, which would interpret the exact value of $c(\rho)$ (possibly up to units) in terms of the objects that one intuitively expects to enter into such a formulation? Special cases would already help. In an ideal world, I would like a formulation, which makes it visible how the "ρ-isotypical parts" of the units and of the class numbers are picked out and how one measures the volume of a suitable lattice in the ρ-isotypical part of the units. Two extra demands that I would have of such a formulation are It should be easily visible that for trivial ρ, we recover the analytic class number formula over K and that the product of these conjectures for all irreducible ρ that factor through F, raised to the powers dim(ρ), gives the analytic class number formula over F. If you don't know of a reference, could you give a hint, how one goes about picking the right sublattice of the units? Difficulties: I see two big difficulties in what I am asking for, so if you can't answer the full question, maybe you can address the difficulties one by one or give me examples of special cases where one or the other has been solved? Firstly, if ρ is not defined over $\mathbb{Q}$, then it's not at all clear, how to define the right volume on the sublattice we pick out. My naive picture is that volumes are determinants of some non-degenerate pairing. If I restrict a non-degenerate pairing to the ρ-component of a lattice (I'm happy to base change the lattice to the ring of definition of ρ, even at the risk of losing some information) and ρ is not self-dual, then the pairing will become degenerate, so the determinant that I would expect in the formulation of a precise Stark conjecture would be 0. Secondly, even if all Artin representations are defined over $\mathbb{Q}$, e.g. is the Galois group is C_2, then although it is easy to say what we mean by the 1-isotypical component and the -1-isotypical component of a lattice, the product of the volumes of these will almost never be the volume of the whole lattice, since their direct sum will have finite non-trivial index in the whole lattice. Many thanks in advance!

Status of finite-dimensional Ando's theorem

Szőkefalvi-Nagy's theorem says the following: if A is a contraction on a Hilbert space H, then there exists a unitary U on a Hilbert space $H'\supset H$ for which $A^n=P_HU^nP_H$ for all $0\le n$. (P_H denotes projection onto H.) If H is finite-dimensional and we only need this to be true for $0\le n\le N$ then this can be modified such that H' is also finite-dimensional (cf. Levy and Shalit - Dilation theory in finite dimensions: the possible, the impossible and the unknown). Ando's theorem (see e.g. Levy-Shalit) says the following: if A and B are commuting contractions on H, then there exist commuting unitaries U and V on $H'\supset H$ for which $A^nB^m=P_HU^nV^mP_H$ for all $0\le n,m$. The construction in the proof is naturally infinite-dimensional even if H is finite-dimensional so a natural question (Problem C in Levy-Shalit) is: if we only need this to be true for $0\le n+m\le N$ then does an analogous modification work to make H' finite-dimensional? Levy-Shalit make this out to be wide-open, as of 2011. My question here is if there are any recent developments in the years since then on this or related problems.

$\mathbf{P} = \mathbf{NP}$, what's the problem?

Let's take the problem of the backpack: $A_1,\ldots ,A_n$ the weights that are integers, and we want to know if we can achieve a total weight of V. We take $$I=\dfrac{1}{2\pi}\int_0^{2\pi} \exp(-iVt)\times (1+\exp(iA_1t))\times\cdots\times(1+\exp(iA_nt)) \, dt.$$ The question then becomes what $I=0$ or $I\geq 1$. Can we not approach the value of I with the method of Monte Carlo, or others? Why are these approaches not succeeding? Remark : it's not difficult to find a good approximation of $B\times t \bmod 2\pi$, where B is a big integer and $t\in [0,2\pi]$, because we know excellent approximation of π.

Midpoint geodesic polygon / Birkhoff curve shortening

I would like to know under what conditions the process of creating a midpoint piecewise geodesic polygon converges on a surface $S \subset \mathbb{R}^3$. S may be assumed smooth, closed, and oriented; or it may be assumed a Riemannian manifold. Let P be a closed geodesic polygon each of whose finite number of edges is a shortest path connecting its endpoint vertices v_i. Moreover, the edges of P are "short" in a sense specified below. P need not be simple, i.e., it may intersect and cross itself. Define the midpoint polygon $M(P)$ for P to have vertices u_i, each the midpoint of the geodesic segment $v_i v_{i+1}$ of P, where u_i is connected to u_{i+1} by a shortest path. I would like the segment $u_i u_{i+1}$ to be the unique shortest path between those points. So assume that $|u_i u_{i+1}|$ is smaller than the injectivity radius of the manifold. (This might require adding new vertices to ensure this condition holds for the next iteration.) In the plane, iterating this midpoint polygon construction is well studied. On a surface (or Riemannian manifold) it plays a role in curve shortening, in particular Birkhoff curve shortening, which he used to prove the existence of a simple closed geodesic [B27]. Subsequently the technique has many uses. For example, Christopher Croke used Birkhoff shortening to find the length of a shortest closed geodesic on a sphere [C88]. The uses I have seen of Birkhoff shortening are on the sphere, not on more general surfaces. Which brings me to the question: Q. Does Birkoff shortening, repeatedly applied to a geodesic polygon on a closed surface S, always converge (perhaps to a point)? If so, always to a closed geodesic? If not, under what conditions might it not converge? References. [B27] George D. Birkhoff, Dynamical Systems, AMS, 1927. p.135ff. [C88] Christopher B. Croke, "Area and the length of the shortest closed geodesic." J. Differential Geom., Volume 27, Number 1 (1988), 1-21.

Convex polygon shadows: Shortest equivalent segments

Let P be a convex polygon. Q1. What is the shortest collection of line segments S inside P with the property that both P and S have the same sequence of orthogonal shadows as P and S rotate? An orthogonal shadow is cast by parallel light rays. For example, for P a unit-square, the X below has length $2 \sqrt{2}$, less than the perimeter 4 of P, but casts the same shadows: every lightray that intersects ∂P intersects S; every lightray that intersects S intersects ∂P: Q2. Is S always connected? Clearly it must span the vertices of P. Q3. Is S the medial axis of P? Medial axis. Fig.5.1(b) from Discrete and Computational Geometry. I feel I should know or be able to find the answers to these questions, but I am not hitting on the appropriate search terms. My real interest is in $\mathbb{R}^3$, but first let's explore $\mathbb{R}^2$. Answered by Gerry Myerson: Q1: Open problem Q2: Not necessarily connected Q3: No

The "Smallest" open Diophantine Equation, a potential approach

In this question, Bogdan Grechuk found the "Smallest" open Diophantine equation, where size is determined by taking absolute values of all coefficients, then substituting 2 into all variables. The equation is $y(x^3-y)=z^3+3$. There are a couple of different reformulations of this problem, for example "Is there any two numbers whose sum is a cube and whose product is three more than a cube?" However, one direction where I have begun to make progress is to reframe the equation as: $yx^3=z^3+y^2+3$. Taking this equation modulo 27, it can be shown that (proof on request): 1) y is not 0, 1, or 8 mod 9 (note in particular this forces y to not be a cube) 2) If y is divisible by 3, then y is 6 or 21 mod 27 Let v be the square-free part of y^2+3. Modulo v, the equation becomes $yx^3=z^3$, so either v divides x and z, or $y=(\frac zx)^3$. In the former case, this implies $v^3|y^2+3$, which seems extremely unlikely due to how v was defined (though I'm not sure how to prove that). In the latter case, we have a third condition on y: 3) y must be a cube mod v. I have tested all values of y up to 1000 so far, and no values of y satisfy all three conditions. So my question is: Can it be proven that there is no integer y which satisfies all three constraints? And a follow up question for the extra case: Can y^2+3 be a 3-Powerful number?

Stronger conjectured inequality for area of a polygon

Four years ago, I proposed an inequality related to area and sides of a polygon. After computer checking, I conjecture that the previous inequality can be strengthened as follows: Let $A_1A_2\cdots A_n$ be an arbitrary polygon, then:

$$4(\tan\frac{\pi}{n})Area(A_1A_2\cdots A_n) \le \sum_{i=1}^n(A_iA_{i+1})^2-\frac{1}{n-2}\sum_{i=1}^n(A_iA_{i+1}-A_{i+1}A_{i+2})^2$$ Question: Can you prove this conjectured inequality? PS: I also found that for an equiangular convex pentagon, $Area(ABCDE)=\frac{1}{4}(\cot\frac{\pi}{5})(a^2+b^2+c^2+d^2+e^2-\frac{(a-b)^2+(b-c)^2+(c-d)^2+(d-e)^2+(e-a)^2}{\sqrt{5}})$

Resources where one can find open problems in Analytic Number Theory

Edit: I have asked this question separately because I am in need of some resources which focus on analytic number theory only.So, this question is not a duplicate of:Resources where I can find open problems in number theory along with their level of difficulty as I am in looking for websites/books/blogs in Analytic Number Theory only. I don't have much knowledge of other branches of number theory. I have completed my master's in mathematics a couple of years ago from a good university of my country but due to very strong personal and professional reasons I couldn't get admitted to grad school despite having a good academic background. I have a really good background in analytic number theory. I have studied 1 course in Sieve Theory, 2 courses which were based on 2 volumes of Apostol's Number Theory books. I will start a course in Automorphic Forms soon. I don't have guidance of any professor right now and I want to try working on an open problem in Analytic Number Theory. Can you please let me know of resources(websites/ blogs/books) where I can find open problems in analytic number theory to work on? Since, I don't have a guidence of a prof. due to various reasons, these resources will really help me. Thank you!

A conjecture on consistent monotone sequences of polynomials in Bernstein form

A Conjecture In the following, a polynomial $P(x)$ is written in Bernstein form of degree n if it is written as- $$P(x)=\sum_{k=0}^n a_k {n \choose k} x^k (1-x)^{n-k},$$ where $a_0, ..., a_n$ are the polynomial's Bernstein coefficients. The degree-n Bernstein polynomial of an arbitrary function $f(\lambda)$ has Bernstein coefficients $f(k/n)$. In general, this Bernstein polynomial differs from f even if f is a polynomial. Let $f(\lambda):[0,1]\to(0,1)$ have a continuous r-th derivative, where $r\ge 1$, and let M be the maximum of the absolute value of f and its derivatives up to the r-th derivative. Let $W_{2^0}(g; \lambda), W_{2^1}(g; \lambda), ..., W_{2^i}(g; \lambda),...$ be a sequence of operators that map a continuous function g on $[0, 1]$ to a bounded function on $[0, 1]$ and converge uniformly to f. Prove or disprove the following conjecture. For each integer $n\ge 1$ that's a power of 2, suppose that there is $D>0$ such that- $$\text{abs}(f(\lambda)-B_n(W_n(f; \lambda); \lambda)) \le DM/n^{r/2},$$ whenever $0\le \lambda\le 1$. Then there is $C_0\ge D$ such that the polynomials (g_n) in Bernstein form of degree 2, 4, 8, ..., 2^i, ..., defined as $g_n=B_n(W_n(f; \lambda); \lambda) - C_0 M/n^{r/2}$, converge from below to f and satisfy: $(g_{2n}-g_{n})$ is a polynomial with nonnegative Bernstein coefficients once it's rewritten to a polynomial in Bernstein form of degree exactly $2n$. Equivalently (see also Nacu and Peres (2005)), there is $C_1>0$ such that the inequality- $$\sum_{i=0}^n \left(W_{2n}\left(f; \frac{k}{2n}\right) - W_n\left(f; \frac{i}{n}\right)\right)\sigma_{n,k,i}\ge -C_1 M/n^{r/2},\tag{PB}$$ holds true for each integer $n\ge 1$ that's a power of 2 and whenever $0\le k\le 2n$, where $\sigma_{n,k,i} = {n\choose i}{n\choose {k-i}}/{2n \choose k}=\mathbb{P}(X_k=i)$ and X_k is a hypergeometric($2n$, k, n) random variable. C_0 or C_1 may depend on r and the sequence (W_n), but not on f, λ, or n. When C_0 or C_1 exists, find a good upper bound for it. It is also conjectured that the same value of C_0 (or C_1) suffices when f has a Lipschitz continuous $(r-1)$-th derivative and M is the maximum absolute value of f and the Lipschitz constants of f and its derivatives up to the $(r-1)$-th derivative. Background I asked this question in order to solve the so-called Bernoulli factory problem, described next. We're given a coin that shows heads with an unknown probability, λ. The goal is to use that coin (and possibly also a fair coin) to build a "new" coin that shows heads with a probability that depends on λ, call it $f(\lambda)$. This is the Bernoulli factory problem, and it can be solved only if f is continuous (Keane and O'Brien 1994). However, since I asked this question I have found a Bernoulli factory algorithm that I believe is general enough to cover all the cases that this conjecture would help solve. Since this conjecture may be of broader interest, though, I leave this question open. See also my other open questions about the Bernoulli factory problem. Special Cases The conjecture may be trivial to prove if the convergence rate of W_n is $O(1/n^{r/2})$. It may also be easy to prove if W_n or $B_n(W_n)$ preserves polynomials of degree $(r-1)$ or less. The conjecture is not so easy to prove in many other cases (e.g., when W_n converges arbitrarily slowly to f). Results Here are results that correspond to the conjecture. If $r=1$ and $W_n=f$, then $C_0 = (1+\sqrt{2})$ (Nacu and Peres 2005), even in the Lipschitz case. If $r=2$ and $W_n=f$, then $C_0 = 1/2$ (Nacu and Peres 2005). If $r=2$ and $W_n=f$, then $C_0 = 1/7$ for every $n\ge 4$ (see "Proofs for Polynomial Building Schemes"). An example for $r=3$ and $W_n=2 f - B_n(f)$*, suggests $C_1 = 0.3078$. In the linked page, it's stated that it's useful to find raw and central moments of hypergeometric random variables, and to find images of λ^i ($k=2n\lambda$) under the left-hand side of (PB), if that left-hand side is a linear operator. The determinant of the sum of normal matrices

Given two normal matrices $A,B\in M_n({\mathbb C})$ whose respective spectra are $(\alpha_{1},\ldots,\alpha_{n})$ and $(\beta_{1},\ldots,\beta_{n})$, is it true that $\det(A+B)$ belongs to the convex hull of the set of numbers $$\prod_{i=1}^n(\alpha_i+\beta_{\sigma(i)}),$$ as σ runs over the set ${\mathfrak S}_n$ of permutations of $\{1,\ldots,n\}$? Nota. It is known (see Exercise 101) that the trace of AB belongs to the convex hull of the set of numbers $$\sum_{j=1}^n\alpha_{j}\beta_{\sigma(j)},\qquad\sigma\in {\mathfrak S}_n.$$

What is the current status on bad tangent cones at isolated singularities?

Let $M^8 \subset B^9 \setminus \{ 0 \} \subset \mathbf{R}^9$ be a properly embedded, stable minimal hypersurface. Suppose that $0 \in \overline{M}$ is an isolated singularity of the surface. Question. (i) Are the tangent cones at the origin regular, that is $\operatorname{sing} \mathbf{C} = \{ 0 \}?$ (ii) If one cone in $\operatorname{VarTan}(\lvert M \rvert,0)$ is regular, is there a 'direct' way of showing that they must all be regular? (By 'direct' I would mean without going via uniqueness of tangent cones à la Lojasiewicz-Simon.) I believe (i) used to be an open question, but I am curious about its current status or partial progress. The Schoen-Simon regularity theory implies that the cones are either regular or cylindrical of the form $\mathbf{C}^7 \times \mathbf{R}$. Correction. Otis Chodosh pointed out in his answer that this is incorrect. The aforementioned regularity theory of Schoen-Simon shows that the singular set of every tangent cone $\mathbf{C} \in \operatorname{VarTan}(\lvert M \rvert,0)$ is one-dimensional, but it can consist of several rays, one for each singularity in the link of the cone. It's the tangent cones taken at these rays that are cylindrical, of the form described above.

Are there any open sourced or crowd source math research projects?

I’m looking for open source math research projects as I know computer science students can easily have access to material they can contribute to but this is not the case with math as far as I’m aware. But I am looking for a possible answer with open source or crowd sourced math research projects that someone in their last year of getting a bachelors or during a Masters could contribute to. Given they have the ability that is.

Open problems in type theory

I am only a beginner in the field of type theory, and I'm wondering if the community could point me out a few open problems in the field. I have a good background in logic, in particular, proof theory and I have a reasonable knowledge on category theory. While I am interested in homotopy type theory, I'd like to receive answers that point to flavors of type theory other than HoTT because open problems in HoTT are not difficult to find on the web (problems in HoTT are still welcome though). This is my very first question in this site so please feel free to edit, point mistakes and criticize my question. Thank you for your attention!

Approximating spectra of (finite rank pertubations of) Laurent operators by spectra of (pertubations of) periodic finite operators

A tridiagonal matrix is a matrix which only has elements on three diagonals. So for $\alpha, \beta, \gamma \in \mathbb{C}$ consider the bi-infinite tridiagonal Laurent operator T with $\beta $ on the diagonal given by. \begin{pmatrix} \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \dots & \alpha & \beta & \gamma & 0 & 0 & 0 & \dots \\ \dots & 0 & \alpha & \beta & \gamma & 0 & 0 & \dots\\ \dots & 0 & 0 & \alpha & \beta & \gamma & 0 & \dots\\ \dots & 0 & 0 & 0 & \alpha & \beta & \gamma & \dots \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ \end{pmatrix} General theory tells us that T is invertible if and only the symbol curve (which is in this case is an ellipsis) given by $ \{ z \in \mathbb{T} \mid \frac{\alpha}{z} + \beta + z \gamma \} $ does not enclose 0. In finite dimensions, we can consider the periodic version T_n. For example T_5 looks as follows: \begin{pmatrix} \beta & \gamma & 0 & 0 & \alpha \\ \alpha & \beta & \gamma & 0 & 0 \\ 0 & \alpha & \beta & \gamma & 0 \\ 0 & 0 & \alpha & \beta & \gamma \\ \gamma & 0 & 0 & \alpha & \beta \\ \end{pmatrix} Now, when n tends to ∞ then the spectra of the periodic versions $\sigma(T_n)$ approximate the spectrum of the Laurent operator T. In the sense that in Haussdorff distance it holds that $$ \sigma(T_n) \to \sigma(T). $$ This can for example be seen by Fourier Transform. Now, suppose that I add finitely many diagonal terms. I.e. the matrix $K = \text{diag}(K_{1,1}, K_{2,2} , \dots, K_{m,m})$. Then it is a Theorem (see https://link.springer.com/article/10.1007/BF01275512, Corollary 1.3) that $$ lim_{n \to \infty} \left(\sigma(T_n + P_n K P_n) \cup \sigma(T) \right) \to \sigma(T+K). $$ Here P_n is the projection onto the n sites of T_n. But in general it is conjectured (https://link.springer.com/article/10.1007/BF01275512, Conjecture 7.3) that $$ lim_{n \to \infty} \left(\sigma(T_n + P_n K P_n) \right) \to \sigma(T+K). $$ Meaning that the finite system can also approximate the symbol curve as was the case without the pertubation. What is the status of this conjecture? And in the case $m=1$ where the pertubation is only a single entry, how could one go about proving it? The reason I am interested is given on page 18 in here https://arxiv.org/pdf/2206.09879.pdf, where one can see that these question can help answer to what extend the spectra of some infinite volume open quantum systems are approximated by their finite volume periodic counterparts.

Finding an optimal covering trail for the set $\{0,1,2,3\}\times\{0,1,2,3\}\times\{0,1,2,3\}$

Here is a key question (i.e., Question 2 below) that, if correctly answered, would let me support a very general conjecture on a wide class of related problems, a conjecture that I have never shared before. In the Euclidean space $\ \mathbb{R}^3,\ $ let $$ \mathcal H(4,3)\ :=\ \{0,1,2,3\}\times\{0,1,2,3\}\times\{0,1,2,3\} \,\ \subseteq\,\ \mathbb R^3 $$ We consider the family of all the distinct straight lines that joins at least two elements of $\mathcal{H}(4,3)$ (i.e., we need to take into account all the lines that pass through two distinct points among the 64 given elements of the above mentioned cubic lattice). Now, let us call $\mathcal{I_2}(4,3):=\{S_1,S_2, \dots, S_{t-1}\, S_t\}$ the set of all the (distinct) intesections of the family of lines above. Question 1: Which is t, the cardinality of $\mathcal{I_2}(4,3)$? Question 2: If we check by brute force all the possible polygonal chains consisting of 21 or 22 line segments (how many?), whose vertices always belong to $\mathcal{I_2}$, will we find at least one covering trail for $\mathcal{H}(4,3)$ (i.e., is it possible to draw at most 22 consecutive links starting and ending on the vertices of $\mathcal{I_2}$ and joining in this way all the 64 elements of the set $\mathcal{H}(4,3)$?)? Current results: I have showed that we can constructively solve the problem by Question 2 with a polygonal chain of length 23 or less, 23 lines" /> whereas it is not possible to find any solution spending less than 21 lines (trivial lower bound)1. By improving my current upper bound, I would finally be able to strongly conjecture that the link length of any minimum-link covering trail for any set of $\{0,1,2,\dots,n-1\}\times\{0,1,2,\dots,n-1\} \times \dots \times\{0,1,2,\dots,n-1\}$ in $\mathbb{R}^k$ is equal to $\frac{n^k-1}{n-1}+n-3$ (here we are assuming that $n \in \mathbb{N}-\{0,1,2\}$ and $k \in \mathbb{N}-\{0,1\}$). Otherwise, if we will be able to show that it is not possible to improve my upper bound of 23 lines, I would infer that the general solution for the $\{0,1,2,\dots,n-1\}\times\{0,1,2,\dots,n-1\}\times \dots \times\{0,1,2,\dots,n-1\}\subset \mathbb{R}^k$ points problem is given by $\frac{n^k-1}{n-1}+(k-1)\cdot(n-3)$. I am persuaded that the 22 lines solution is likely to exist (or at least I strongly believe that it does not exist any covering trail consisting of only 21 links that covers $\mathcal{H}(4,3)$), but I would not have many arguments to support my general claim without confirming the above by brute force testing. Moreover, I have constructively proven that the link-length of the optimal covering trail for the set $\{0,1,2,3,4\}\times\{0,1,2,3,4\}\times\{0,1,2,3,4\} \subset \mathbb{R}^3$ belongs to $\{31, 32, 33, 34, 35, 36\}$, see the figure below 2. Related OEIS sequence: A318165. P.S. It is trivial to point out that all the S_i, for any $i=1,2,...,t$, necessarily belong to the

Conjecture on the unsolvability of the $\{3 \times 3 \times \cdots \times 3\} \subseteq \mathbb{R}^k$ dots problem starting from the central point

In 2020 (see Solving the 106 years old 3^k points problem with the clockwise-algorithm, JFMA, 3(2), p. 96), I conjectured that, in the Euclidean space $\mathbb{R}^k$, we can cover any given set of 3^k points $\mathcal{H}(3,k):=\{3 \times 3 \times \cdots \times 3\}\subseteq \mathbb{R}^k$ with an optimal polygonal chain $\mathcal{P}\left(\frac{3^k-1}{2}\right):=\rm{S}_1$-$\rm{S}_2$-$\rm{S}_3$-$\cdots$-$\rm{S}_{\left(\frac{3^k-1}{2}\right)}$-$\rm{S}_{\left(\frac{3^k+1}{2}\right)}$ having minimum link-lenght, whose two endpoints belong to $\mathcal{H}(3,k)$, if and only if $$\rm{S}_1 \not\equiv (1,1,\dots,1) \wedge \rm{S}_{\left(\frac{3^k+1}{2}\right)} \not\equiv (1,1,\dots,1).$$ I suspect that the above would not be so hard to be proven, since Theorem 1 by 1 and Theorem 2.1 by Minimum-Link Covering Trails for any Hypercubic Lattice imply that any optimal covering trail for $\mathcal{H}(3,k)$ has to be a sequence of consecutive (connected) line segments joining $\frac{3^k-3}{2}$ times 2 unvisited points of $\mathcal{H}(3,k)$ and only one time 3 new points (no exceptions). Conjecture: For any $k \in \mathbb{N}-\{0,1\}$, there does not exist any $\frac{3^k-1}{2}$ links (optimal) polygonal chain $\mathcal{P}\left(\frac{3^k-1}{2}\right):=\rm{S}_1$-$\rm{S}_2$-$\rm{S}_3$-$\cdots$-$\rm{S}_{\left(\frac{3^k-1}{2}\right)}$-$\rm{S}_{\left(\frac{3^k+1}{2}\right)}$ that visits all the points of the set $\mathcal{H}(3,k)$ and such that $\rm{S}_1 \not\equiv (1,1,\dots,1) \wedge \rm{S}_{\left(\frac{3^k+1}{2}\right)} \not\equiv (1,1,\dots,1)$. Now, since we need to start from the central point $C:=(1,1,\dots, 1) \in \mathbb{R}^k$ (otherwise, we could simply reverse the chosen sequence of the nodes of $\mathcal{P}$), we observe that the link $\rm{S}_1$-$\rm{S}_2$ visits no more that two points and the same thing must necessarily occur for $\rm{S}_2$-$\rm{S}_3$, but is that true up to $\rm{S}_{\left(\frac{3^k-1}{2}\right)}$-$\rm{S}_{\left(\frac{3^k+1}{2}\right)}$, for any $k \in \mathbb{N}-\{0,1\}$?

Do primes of the form $4k+1$ ever lead the greatest prime factor race?

Analogous to Chebyshev's race between primes, I examined the race between primes in the greatest prime factors, GPF, of natural numbers. Similar to the regular prime race, in the GPF race, the proportion of prime of both forms is roughly 50% each. However, unlike the regular prime race where the race is equal (A038691) or changes lead between primes of the form $4k+1$ and $4k+3$ (A096628) in the GPF race, $4k+3$ dominates. For $n \le 3 \times 10^{10}$, there are 14970975209 numbers the GPF is of the form $4k+1$ and 15029024755 numbers where GPF is of the form $4k+3$ and up till this point, there is not a single instance where primes of the form $4k+1$ equal or take the lead in the race. Let $f_1(n)$ and $f_3(n)$ be the number of natural numbers $\le n$ in which the GPF is of the form $4k+1$ and $4k+3$ respectively. The difference between the number of GPFs on these two forms appeared to increase in a very orderly manner as shown in the graph below. Question 1: Does the GPF race ever become equal or change the lead i.e. is there an n such that $f_1(n) = f_3(n)$? Clearly, the graph is sub-linear. I applied different curve fitting models to this data to have an idea of the growth rate. The best fit was given by $$ f_3(n) - f_1(n) \approx an^b $$ where $a \approx 0.1785$ and $b \approx 0.8122$. This experimental model has a very high $R^2 = 0.9999958$. If this is close to the true growth rate then, prime of the form $4k+1$ will always lag behind in the GPF race. Question 2: What is the true growth rate of $f_3(n) - f_1(n)$? Check out the interesting comments by Greg Martin (1 2) and Eric Naslund (1 2 3) in the linked question in MSE. Note: Was posted on MSE but was unanswered. Hence posting in MO.

Is it still not known whether the construction of shortest nonzero vector of a lattice w.r.t. l^2-norm is NP-hard?

It was shown in P. van Emde Boas, Another NP-complete partition problem and the complexity of computing short vectors in a lattice that the construction of a shortest nonzero vector of a Euclidean lattice w.r.t. the L^{∞}-norm is NP-hard. But for the L^2 norm, is this question still open? Can anyone explain the difficulty and progress in this problem?

Traveling salesperson problem algorithm

I was wondering something, let's say in a symmetric distance matrix of a sample of TSP, there was a sure algorithm that could remove between 30% to 80% of the values (distances) that wouldn't definitely be used in order to get the shortest routes in the end, would such algorithm be valuable and something new? It will definitely reduce many combinations of

routes but I don't think 80% would be always even close to enough to turn samples like a million cities into a P problem.

Places where one can post open problems

(This must have been asked before and exist somewhere in Community Wiki, but I can't find it...) Where can you post open (math) problems? And what are the advantages and disadvantages? Example: This place (and Math StackExchange), duh. Example: The journal AMM had a corner "Unsolved Problems", but no longer. (Editor Stan Wagon told me that he doesn't know any math journal accepting unsolved problems.) Example: But then, probably any journal will accept a small "Open Questions" section after a research article. Example: USENET once had an useful group. The group still exists. (Yes, I'm that old...) Example: Other social media, e.g. Reddit has a math sub.

Is there a 7-regular graph on 50 vertices with girth 5? What about 57-regular on 3250 vertices?

The following problem is homework of a sort -- but homework I can't do! The following problem is in Problem 1.F in Van Lint and Wilson: Let G be a graph where every vertex has degree d. Suppose that G has no loops, multiple edges, 3-cycles or 4-cycles. Then G has at least d^2+1 vertices. When can equality occur? I assigned the lower bound early on in my graph theory course. Solutions for $d=2$ and $d=3$ are easy to find. Then, last week, when I covered eigenvalue methods, I had people use them to show that there were no solutions for $d=4$, 5, 6, 8, 9 or 10. (Problem 2 here.) I can go beyond this and show that the only possible values are $d \in \{ 2,3,7,57 \}$, and I wrote this up in a handout for my students. Does anyone know if the last two exist? I'd like to tell my class the complete story.

Conjecture about primes and Fibonacci numbers

I posted this conjecture on math.stackexchange, but I received no answer proving or disproving it: if $ m > 4 $ is a positive integer not divisible by $ 2 $ or $ 3 $, it's ever possible to find a positive integer $ n $ such that the difference of the $ 2 $ Fibonacci numbers $ F_{m+n}-F_n $ is a prime number. Various example of $ [m, n] $, with the smallest n, are: $[5,1],[7,3], [11,4], [13,5], [17,3],..., [619,1353],...,[2011,6629]...$. The numerical evidence supporting that is quite good; I need to thank @Peter for his great findings searching for counterexamples. Here you'll find all the values of n for $m < 3000$ supporting the conjecture (the hardcases are at the bottom). Here the Oeis sequence about the difference of Fibonacci numbers being a prime I converted the primes found that way in the Zeckendorf representation and they are an alternating sequence of $ 1 $ and $ 0 $ ending with two adjacent $ 0 $ and $ 1 $ (and eventually just various $ 0 $). Looking for some known result, I found this article: "Primes as Sums of Fibonacci Numbers", I asked about this conjecture to one of the authors and this was the answer: "The conjecture can be stated as follows. First, for $ k≥1 $, we define K to be the string of length $2k-1$, starting with 1 and containing $1s$ and $0s$ alternatingly.Is there always a prime number p having the Zeckendorf expansion $K0010..0$? This would imply the "showcase result" of our paper, "for each large enough k, there is a prime number p that is the sum of exactly k different, non-adjacent Fibonacci numbers". I don't see a way how to prove this, as it amounts to finding a prime number in a very sparse subsequence (growing exponentially). In our paper the problem was easier, since there are "many" integers whose Zeckendorf expansion has length Ck (C some constant involving the golden ratio) and exactly k digits equal to 1." Do you have any idea?

$\lim_{b \rightarrow \infty} {^{b}a} \in \mathbb{Q}_p$ for any $a \in \mathbb{Z}^+$?

$\newcommand\tetra[2]{{^{#1}{#2}}}$In a recent discussion on the Tetration Forum (see https://math.eretrandre.org/tetrationforum/showthread.php?tid=1703&page=2), it has been pointed out how my results on the constancy of the "congruence speed" of the integer tetration $\tetra b a$ (a peculiar property of hyper-4 described in The congruence speed formula), would imply that $\lim_{b \rightarrow \infty} \tetra b a$ is always an element of the set $\mathbb{Q}_p$. At the time, I did not fully realize the power of this breakthrough, since my original goal was only to find a function $V(a) : \mathbb{Z}^+-\{M\} \rightarrow \mathbb{Z}^+$, where $M = \{a : a \not\equiv 0 \pmod {10} \land a \neq 1\}$, but after a little search, I have seen that this is a general open problem, explicitly solved only for a few cases (since 1953, for $a:=2$). Furthermore, I have not managed to find any proof that even $\lim_{b \rightarrow \infty} \tetra b 6$ is a rational p-adic number (or rather an irrational one, disproving the aforementioned claim). Now, my first concern is if I am wrong and $\lim_{b \rightarrow \infty} \tetra b 6$ has already been proven to be an element of $\mathbb{Q}_p$ (or not), while my general request here is to know more about the implications of Equation 16 on page 15 of Ripà and Onnis - Number of stable digits of any integer tetration on the above mentioned general open problem (and related topics).

Furstenberg's Conjecture on 2-3-invariant continuous probability measures on the circle

Hillel Furstenberg conjectured that the only 2-3-invariant probability measure on the circle without atoms is the Lebesgue measure. More precisely: Question: (Furstenberg) Let μ be a continuous probability measure on the circle such that $$\int_{S^1} f(z) d\mu = \int_{S^1} f(z^2) d\mu = \int_{S^1} f(z^3) d\mu, \quad \forall f \in C(S^1).$$ Is μ the Lebesgue measure? The assumption implies that the Fourier coefficients $\hat\mu(n)$ satisfy $$\hat\mu(n) = \hat \mu(2^k3^l n), \quad \forall k,l \in \mathbb N, n \in \mathbb Z.$$ Furstenberg's question is known to have an affirmative answer if one makes additional assumptions on the entropy of the measure. The basic strategy is usually to show that a non-vanishing (non-trivial) Fourier coefficient implies the existence of an atom. The standard tool to construct atoms in a measure on the circle is Wiener's Lemma, which says that as soon as there exists $\delta>0$ such that the set $\lbrace n \in \mathbb Z \mid |\hat\mu(n)| \geq \delta \rbrace$ has positive density in $\mathbb Z$, μ has an atom. More precisely, the following identity holds: $$\sum_{x \in S^1} \mu(\lbrace x \rbrace)^2 = \lim_{n \to \infty} \frac1{2n+1} \sum_{k=-n}^n |\hat \mu(k)|^2.$$ Clearly, $$|\lbrace 2^k3^l \mid k,l \in \mathbb N \rbrace \cap [-n,n] | \sim (\log n)^2 $$ so that Wiener's Lemma can not be applied directly. My question is basically, whether this problem can be overcome for any other subsemigroup of $\mathbb N$. Question: Is there any subsemigroup $S \subset \mathbb N$ of zero density known, such that every S-invariant continuous probability measure on S^1 is the Lebesgue measure? What about the subsemigroup generated by $2,3$ and 5?

Normal curvature of Veronese embedding

Is it true that the Veronese embedding minimizes the maximal normal curvature among all smooth embeddings $\mathbb{R}\mathrm{P}^n\hookrightarrow \mathbb{S}^N$? Remarks The Veronese embedding $\mathbb{R}\mathrm{P}^n\hookrightarrow \mathbb{S}^{(n+3)\cdot n/2}$ describes a minimal surface. Its induced metric tensor $=2\times$(canonical metric on $\mathbb{R}\mathrm{P}^n$). It sends geodesics of $\mathbb{R}\mathrm{P}^n$ to circles with curvature $\kappa_n=\sqrt{\tfrac{n-1}{n+1}}$ in the sphere; in particular, its normal curvature κ_n at every point in every direction. The same question can be asked about $\mathbb{C}\mathrm{P}^n$ and $\mathbb{H}\mathrm{P}^n$. The value κ_n can be visualized the following way. Suppose d_n is the spherical distance between vertices of an inscribed equilateral n-simplex in $\mathbb{S}^{n-1}$. Then κ_n is the curvature of a spherical circle of radius $d_n/2$. Note that $d_n\to \tfrac\pi2$ and $\kappa_n\to 1$ as $n\to\infty$. I can solve the case $n=2$. Now it is written; any comments are welcome. In fact any submanifold with normal curvature $<\kappa_2=\tfrac1{\sqrt{3}}$ is diffeomorphic to the standard sphere. (In this case the curvature of the induced metric is $\tfrac14$-pinched; so it is sufficient to show that the submanifold is simply connected.) This question is from my paper (see 1.4), and it was motivated by Gromov's "Isometric immersions with controlled curvatures".

Open problem: $\log n$ factor in Binomial empirical process

The following problem was considered in Cohen and Kontorovich, "Local Glivenko-Cantelli", https://arxiv.org/abs/2209.04054, to appear in COLT 2023 (henceforth, CK'23). Let Y_j, $j\in\mathbb{N}$ be a sequence of independent $\operatorname{Binom}(n,p_j)$ random variables, where $n\in\mathbb{N}$ and $1/2\ge p_j\downarrow 0$ as $j\to\infty$. Since $\mathbb{E} Y_j=np_j$, let us consider the centered, normalized process $\bar Y_j:= n{^{-1}} Y_j-p_j $. Finally, we define Δ_n to be the expected uniform absolute deviation: $$ \Delta_n := \mathbb{E}\sup_{j\in\mathbb{N}}|\bar Y_j|. $$ CK'23 gave an exact characterization of the $p\in[0,{\frac12}]^{\mathbb{N}}_{\downarrow0}$ (that is, $p\in[0,{\frac12}]^{\mathbb{N}}$ with $p_j\downarrow 0$) for which $\Delta_n\to0$ as $n\to\infty$. Namely, they defined the functional $$ T(p) := \sup_{j\in\mathbb{N}}\frac{\log (j+1)}{\log(1/p_j)} . $$ and showed that $\Delta_n\to0$ iff $T(p)<\infty$. They also gave the finite-sample bound $$ \Delta_n \le c\left(\sqrt{\frac{S(p)}{n}} +\frac{T(p)\log n}{n} \right), \qquad n\ge \mathrm{e}^3 \qquad(*) $$ where $c>0$ is an absolute constant and $$ S(p) := \sup_{j\in\mathbb{N}}p_j\log (j+1). $$ We conjecture that the $\log n$ factor in $(*)$ is superfluous. This conjecture is motivated by the asymptotic lower bounds $$ \liminf_{n\to\infty} \sqrt n \Delta_n \ge c\sqrt{S(p)}, $$ $$ \liminf_{n\to\infty} n \Delta_n \ge cT(p) , $$ where $c>0$ is a universal constant. This shows that beyond the conjecturally removable $\log n$ factor, $(*)$ is tight up to constants. Open problem. Is the $\log n$ factor in $(*)$ necessary, or can it be removed? UPDATE 21-Jul-2023. This was presented as an open problem at COLT'23: https://proceedings.mlr.press/v195/cohen23b.html Within days of the announcement and independently of each other, Moïse Blanchard, Václav Voráček, and Jaouad Mourtada obtained essentially the same substantial improvement. Formally, their results show that there is an absolute $c_1>0$ such that for any constant $c>0$ there is an n_0 such that for all $n>n_0$ there is a sequence $p\in[0,{\frac12}]^{\mathbb{N}}_{\downarrow0}$ for which $$ \Delta_n(p) > c\sqrt{\frac{S(p)}{n}} + c_1\frac{T(p)\log n}{n\log\log n}. \qquad(**) $$ This certainly dashes any hope of removing the $\log n$ factor in $(*)$ entirely; the best one could aim for is replacing it by $\log(n)/\log\log(n)$. This raises a number of fascinating questions. First: Is there a fixed sequence p_j (i.e., independent of n) for which $$ \liminf_{n\to\infty} \frac{n\log\log n}{\log n} \Delta_n \ge cT(p) , $$ where $c>0$ is a universal constant? Second: Is there a functional $\tilde T(p)$ and a monotonically increasing $\varphi:\mathbb{N}\to \mathbb{N}$ such that $$ c\tilde T(p) \le \liminf_{n\to\infty} \varphi(n) \Delta_n \le \limsup_{n\to\infty} \varphi(n) \Delta_n \le c'\tilde T(p) $$ for absolute constants $c,c'>0$? UPDATE 25-Jul-2023. We congratulate Moïse Blanchard on resolving the gap entirely, by exhibiting a p for which $$ \Delta_n(p) > c\sqrt{\frac{S(p)}{n}} + c_1\frac{T(p)\log n}{n} $$ (all constants and quantifiers as in $(**)$). Additionally, it has been pointed out to us by Moïse, Václav, Jaouad that the "lower bound" $ \liminf_{n\to\infty} n \Delta_n \ge cT(p) $ is trivial, since for nontrivial p, Δ_n will be at least $1/\sqrt n$ for n large enough, meaning that $\liminf_{n\to\infty} n \Delta_n =\infty$. We have

corrected this with the following non-trivial lower bound: Theorem (Cohen, K., 2023): There is an absolute constant $c>0$ such that $$ \Delta_n(p) \ge c\left(1\wedge\frac{T}{n}\right), $$ for all $n\in\mathbb{N}$ and $p\in[0,{\frac12}]^{\mathbb{N}}_{\downarrow0}$. Thus, currently, the two open questions are: Is there a fixed sequence p_j (i.e., independent of n) for which $$ \Delta_n(p) \ge c\left(1\wedge\frac{T\log n}{n}\right), $$ for some $c>0$? Is there a functional $\tilde T(p)$ and a monotonically increasing $\varphi:\mathbb{N}\to \mathbb{N}$ such that $$ \Delta_n \le c\left(\sqrt{\frac{S(p)}{n}} +\frac{\tilde T(p)}{\varphi(n)} \right) $$ and $$ \Delta_n(p) \ge c'\left(1\wedge\frac{\tilde T(p)}{\varphi(n)}\right), $$ for absolute constants $c,c'>0$ and all $n\in\mathbb{N}$, $p\in[0,{\frac12}]^{\mathbb{N}}_{\downarrow0}$?

Books/blogs/websites that have open problems in Algebraic geometry

I got admitted in a PhD program in Europe last year. But due to serious mental health issues , I was deemed unfit by the mathematics department to continue the program. I am from a 3rd world nation and I got these problems there due to some issues I would not like to mention. So, I have decided to take a break and work on my health and to take a job to sustain myself before I apply again. The reason why I want to return to mathematics (in future years only not in current or upcoming year) because I love studying mathematics, solving exercises. I have a fine background in abstract algebra and algebraic geometry and I was wondering if you can let me know some books/ websites/ blogs which lists some open problems in Algebraic Geometry? Having to know some problems in algebraic geometry and current literature will help me to keep in touch with the field and a little motivated.

An open problem of Hardy and Littlewood on p-integral means

In Duren's book "Theory of H^p spaces" (MSN) in the comment section after Section 4, it is mentioned that Littlewood and Hardy proved in Some properties of conjugate functions that if u is a harmonic function in the unit disc belonging to the harmonic Hardy space h^p, $0<p\leq 1$. Then the harmonic conjugate of u, call it v satisfies $$ M_p(r,v):= \biggl(\frac{1}{2\pi} \int_{0}^{2\pi} \lvert v(re^{i\theta})\rvert^p d\theta \biggr)^\frac1p= O\bigl(\bigl(\log\frac{1}{1-r}\bigr)^\frac1p \bigr), \,\,\, r\to 1. $$ Furthermore they show that for $p=1,\frac12,\frac13,\dotsc$ the "big-O" cannot be improved to "little-o" by giving a concrete example. Duren then claims that this is an open question for other values of $p\in(0,1]$. Given that the book is written in the '70s I would like to know if this is still an open problem, or if there has been some progress.

What polynomials biject from $\mathbb{N}^{2}$ to $\mathbb{N}$?

Perhaps there are none with integral coefficients; so let us admit rational coefficients. The map $(x, y) \mapsto x + \frac{1}{2}(x + y)(x + y + 1)$ is well known, and swapping x and y in the formula yields another, so we have two for starters.

Status of Problems in 102 problems in mathematical logic

Is there any location that records the current status of the problems in 102 problems in mathematical logic? Or, better yet, serves as a status board for open problems in mathematical logic? Mathoverflow is nice, but I'd leave it in a heartbeat for a variant that had an 'open problems' section which people could add problems to or mark them as solved as papers got published. I almost just embarrassingly claimed to solve Q62 while writing up my solution to this question even though I should have remembered Harrington solved it. Especially, as I agreed to write up beyond ω parts of his notes up at some point but haven't gotten to it yet.

Different flavours of Vassiliev Conjecture

There is something that puzzles me about "Vassiliev's Conjecture". I am sure I am missing some detail which is obvious to the community, since there are several tightly related kind of results around Vassiliev invariants that I am not sure how to connect. Genuine Vassiliev's Conjecture [GVC] Let $\mathcal{K}$ be the space of knots in 3 dimensions. Let $\sim_n$ be the equivalence relation on $\pi_0(\mathcal{K})$ that identifies knots that cannot be distinguished by Vassiliev invariants of order $\le n$. We have a tower of surjections: $$ \pi_0(\mathcal{K}) \to \ldots \to \pi_0(\mathcal{K})/ \sim_n \to \pi_0(\mathcal{K})/\sim_{n-1} \to \ldots \to \pi_0(\mathcal{K})/ \sim_1 $$ The Genuine Vassiliev Conjecture states that two different knots can always be distinguished by a Vassiliev invariant. In other words, we require the injectivity of the maps $$ \pi_0(\mathcal{K}) \to \varprojlim_{n \to \infty} \pi_0(\mathcal{K})/\sim_n $$ Chord Vassiliev's Conjecture [CVC] A first line of results in this direction are given by things like Konsevitch Theorem. If $\mathcal{V}_n$ is the set of Vassiliev invariants of order $\le n$, Konsevitch proved that $$\mathcal{V}_n \otimes \mathbb{R} \cong \bigoplus\limits_{s \le n} A^*_s \otimes \mathbb{R} $$ where A_s is a suitable algebra of chord diagrams. There is a little trick we can do to reformulate Konsevitch theorem in terms of our tower. If we consider $\mathcal{V}_n \otimes \mathbb{Q}$ as a subspace of the dual of $\pi_0(\mathcal{K}) \otimes \mathbb{Q}$, we can write (see here): $$ (\pi_0(\mathcal{K})/ \sim_n) \otimes \mathbb{Q} \cong \frac{\pi_0(\mathcal{K}) \otimes \mathbb{Q}}{(\mathcal{V}_n \otimes \mathbb{Q})^{\perp}} \cong (\mathcal{V}_n \otimes \mathbb{Q})^* \cong \bigoplus_{s

\le n} A_s \otimes \mathbb{Q} $$ De Brito and Horel state that there exists a map $A_n \to \ker(\pi_0(\mathcal{K})/\sim_n \to \pi_0(\mathcal{K})/\sim_{n-1})$, where knots up to n-equivalence can be regarded as an abelian group under connected sum. When tensoring over $\mathbb{Q}$, it becomes an isomorphism; this fact, by an easy induction, yields the above formula for $\pi_0(\mathcal{K})/\sim_n$. Thus we will call the Chord Vassiliev's Conjecture the fact that $A_n \to \ker(\pi_0(\mathcal{K})/\sim_n \to \pi_0(\mathcal{K})/\sim_{n-1})$ is an isomorphism. Tower Vassiliev's Conjecture [TVC] At last, there are a few results linking the above tower with the taylor tower of knots. Specifically, Budney et al. proved that there exist maps $\pi_0(\mathcal{K})/\sim_n \to \pi_0(T_{n+1} \mathcal{K})$ that commutes with the tower maps. We call Tower Vassiliev's Conjecture (TVC) the fact that such a map is an isomorphism. Implications Let us denote by [CHL], [CCH], [CHT] the collapse at the second page of the homology, cohomology and homotopy spectral sequence associated with the taylor tower, at least over the antidiagonal. I want to prove some implications between the three vassiliev conjectures, eventually assuming some of the collapsing conditions. Here is what I have tried: [TVC] implies [GVC]. Since we have in isomorphism of towers, we can analogously show the injectivity of the map $$\pi_0(\mathcal{K}) \to \varprojlim_{n \to \infty} \pi_0(T_n \mathcal{K})$$, which is the composite of $\pi_0(\mathcal{K}) \to \pi_0(T_{\infty} \mathcal{K})$ with the projection $$\pi_0(T_{\infty} \mathcal{K}) \to \varprojlim_{n \to \infty} \pi_0(T_n \mathcal{K})$$ I suspect that these maps should be injective for a general reason, which I can't see. For example, it should be the case that $\pi_0(T_{\infty} \mathcal{K})$ is uncountable and $\pi_0(\mathcal{K})$ is countable, which makes injectivity plausible. Unluckily, it seems to me that the connectivity estimates of Goodwillie are not enough to conclude its injectivity. The injectivity of the other map should have to do with the relation between the total homotopy spectral sequence and the truncated ones (converging to $T_n \mathcal{K}$). It seems to me that both sides are given by $ \oplus_p E^{-p,p}_{\infty}$ where the latter is the homotopy spectral sequence; but π_0 of a homotopy limit is not always the limit of π_0, so I am definitely missing something. [TVC] implies [CVC]. The map reformulates as $ A_n \to \ker(\pi_0 T_{n+1} \mathcal{K} \to \pi_0(T_n\mathcal{K}))$. We know that in the homotopy spectral sequence $ A_n \cong E_{n+1,n+1}^2$ and also that $E^1_{n+1,n+1} = \pi_0(\textrm{fib}(T_{n+1}\mathcal{K} \to T_n \mathcal{K}))$. I suspect that using the long exact sequence for the fiber seq and analyzing a bit the spectral sequence should give the result, maybe up to assuming something else on the way. [TVC] implies [CHT]. This is stated explicitly by De Brito-Horel in theorem 6.1. [CCH] implies [CVC]. Indeed, Vassiliev invariants are $\oplus_{p} E^{-p,p}_{\infty}$, where the latter is the cohomology spectral sequence, while chord algebras pop up at the second page of Sinha Spectral sequence (first of Vassiliev) on the same line. Questions How many wrong things have I said? Can you fill in the gaps in my implications? Are there other implications that I am missing? Could you share your perspective on this matter? I feel like mine is somewhat goofy deformation of a solid one. How does the homology spectral sequence fit in this framework? Why has it been so intensively studied? Thank you. Of course, since it is a lot of material, partial answers are ok too.

A question on Giles Gardam counter example to the Unit conjecture of Kaplansky

The unit version of the Kaplansky conjecture is about units in FG where F is a field and G is a torsion free group. In a recent counter example by Giles Gardam, it is given an example of a non trivial unit when $F=F_2$ is the field with 2 elements and G is a finitely presented torsion free group. See this MO post for some discussions on this counter example. The group G in Giles Gardam counterexample is a result of a group extension $Z^3\to G\to Z_2\times Z_2$. So it would be helpful to study some other extensions of Z^3 by this quotient group? Do they generate other examples?

Initial conditions to falsify Rowland's conjecture

Based on the Rowland's paper (A natural prime-generating recurrence), is there any theorem to show that for which initial condition $a(1) = k$ the conjecture can be falsified? For example, for k equals 532 or 801, the conjecture of "only 1 or prime for the recurrent formula $g(n) = a(n)-a(n-1) = \gcd(n, a(n-1))$" does not hold, mentioned in the same paper. In sum, I am wondering if there is any theorem or conjecture to show some properties for (a subset of) such ks.

Density of values of polynomials in two variables

This question is a reposting of a comment I made on Polynomial representing all nonnegative integers. Let $f(x,y)\in \mathbb Q[x,y]$ such that $f(\mathbb Z\times \mathbb Z)$ is a subset of $\mathbb N$ (the nonnegative integers). Let $g(n)$ be the number of elements of $f(\mathbb Z\times \mathbb Z)\cap \lbrace 0,1,\dots, n\rbrace$. How fast can $g(n)$ grow? Is it always true that $g(n)=O(n/\sqrt{\log(n)})$? If true this is best possible since if $f(x,y)=x^2+y^2$ then $g(n)\sim cn/\sqrt{\log(n)}$.

Has there been any progress on this open problem about co-well-poweredness of accessible categories?

On the relations between accessible categories and large cardinal axioms, one big example is the following: Assume the existence of a proper class of strongly compact cardinals. Then every accessible category is co-well-copowered. This can be found, for instance, in the standard reference Makkai-Paré (Acessible categories: The Foundations of Categorical Model Theory). We have Proposition 6.2.2: If pushouts are detectable in $\mathcal{K}$ (that is, the

category of diagrams which have pushouts is accessible), $\mathcal{K}$ is co-well-powered This also follows imitating the argument in Theorem 2.49 of Adamek-Rosicky (Locally presentable and accessible categories). The important result is: Theorem 6.3.8 (M-P): Assume there is a proper class of strongly compact cardinals. Then colimits are uniformly detectable in every accessible category, that is, the subcategory of $\mathrm{Diag}(A)$ (the total category) whose objects are diagrams admiting colimits is accessible. From there we can deduce detectability of pushouts and the result follows. Furthermore, every accessible category being co-wellpowered implies the existence of a proper class of measurable cardinals, as Example A.19 of Locally presentable and accessible categories shows with a counterexample using transitive models of ZC and a formal initial object, assuming there's a maximal measurable cardinal. There's probably an example in Makkai-Paré too but I don't recall any. Thus the large cardinal strength of the assertion "every accesible category is co-well-powered" lies somewhere between "there's a proper class of strongly compacts" and "there's a proper class of measurables", but as far as I know this is an open problem, and even though I by no means have made an exhaustive research on its status, I did some for my bachelor thesis (on the topic of accessible categories, AECs and large cardinals), and haven't been able to find anything at all (except for an article of Bagaria using supercompacts). Has there been any development on this open problem? What is the most likely direction: an argument assuming a proper class of measurables or deriving a proper class of strongly compacts?

An open problem about simple Noetherian rings

The following is a well-known open problem in ring theory (see, for instance, Goodearl, Warfield, 'An introduction to noncommutative Noetherian rings, Appendix, Problem 19) Question: Let R be a left Noetherian simple ring. Can every left ideal be generated by two elements? The history of this problem goes back to the seminal work of Stafford 'Module structure of the Weyl algebra'. In this paper, Stafford showed, among other things, that k being a field of zero characteristic, every left ideal for the Weyl algebras $A_n(k)$ can be generated by two elements. In the same paper, he stated as problem to find large classes of algebras for which his results on the Weyl algebras also hold; in particular, the two-generation property of left ideals. A lot of research has been done on this topic. There are some natural generalizations of Stafford's result for algebras that are similar to the Weyl algebra: the two-generation property of left ideals holds for $k(x_1,\ldots,x_n)\langle \partial_1, \ldots, \partial_n \rangle$, and the subalgebra of $End_k k((x_1,\ldots,x_n))$ generated by $k((x_1,\ldots,x_n))$ and the usual partial derivatives $\partial_1, \ldots, \partial_n$. Bavula showed that the two-generation property for left ideals holds for many generalized Weyl algebras - for example, it holds for the quantum torus $k_q[x^\pm,y^\pm]$, when q is not a root of unity. A natural question, raised in 1980 by Björk, is if we have the two-generation property for left ideals for rings of differential operators on smooth affine varieties. Coutinho and Holland worked on this problem, and showed that every left ideal for such rings can be generated by three elements - and Björk's question is still open. If we consider the Weyl algebra $A_n(D)$ over a division ring D of zero characteristic, we have a similar result, obtained by Byun: every left ideal can be generated by three elements. All of the above are particular cases of rings. The only general result I know, also due to Stafford, is the following: let R be a simple left Noetherian ring with Krull dimension d. Then every left ideal can be generated by $d+1$ elements. I am curious for what reasons there are to believe or not that every left ideal for a simple left Noetherian ring can be generated by two elements. Sure, the results I described above count as positive evidence to believe this fact. However, in my opinion, all those rings above are rather similar in nature: all of them are some natural generalization of the Weyl algebra. So, besides the above discussed positive results and lack of counter-examples, are there other reasons to believe in a positive solution to this open problem?

Conjecture: Given any five points, we can always draw a pair of non-intersecting circles whose diameter endpoints are four of those points

The following question resisted attacks at Math SE, so I thought I would try posting it here. Is the following conjecture true or false: Given any five coplanar points, we can always draw at least one pair of non-intersecting circles coplanar with the points, such that two of the given points are diameter endpoints of one circle, and another two of the given points are diameter endpoints of the other circle. Tangent circles are considered to be non-intersecting. Coincident circles are considered to be intersecting. Example: Another example: I cannot find a counter-example, nor can I prove the conjecture. Remarks: I made a generator of five (pseudo)random points. If, instead, we were given four points, the conjecture would not be true: for example, if the four points were the vertices of an equilateral triangle plus the centre, then we could not draw a pair of non-intersecting circles. The generalized conjecture with $2n+1$ points and n circles is not true. I have asked, and answered, a similar question, which might provide ideas for this question. Context: I was thinking about this question about random points in a disk. Staring at various sets of five points, I came up with this conjecture.

Does the interior of Pascal's triangle contain three consecutive integers?

This question defeated Math SE, so I am posting it here. Consider the interior of Pascal's triangle: the triangle without numbers of the form $\binom{n}{0},\binom{n}{1},\binom{n}{n-1},\binom{n}{n}$. A006987 (which is described here) is a list of the smallest 10000 numbers in the interior of Pascal's triangle, omitting repetitions. It contains 15 instances of two consecutive integers. It contains only one instance of integers separated by 2. But it does not contain three consecutive integers. So I wonder: Does the interior of Pascal's triangle contain three consecutive integers? Conjecture 3.1 of Binomial Collisions and Near Collisions is the conjecture that a list contained in that paper is the complete list of binomials that differ by 1. If this conjecture

is true, this would imply that there are no three consecutive binomial coefficients. But even if this conjecture is unresolved, there might be a way to show that there are no three consecutive binomial coefficients. Maybe proof by contradiction, or a combinatorial argument?

What is the current status of research on the von Neumann's inequality for $n \ge 3$?

Problem Let $(T_1, \ldots, T_n)$ be a tuple of commuting contractions in Hilbert space H. Does a constant $C_n \ge 1$ exist, for which it would be true, that: $$\forall_{p \in \mathbb{C}[x_1, \ldots, x_n]} \quad \| p(T_1, \ldots, T_n) \| \le \ C_n \sup_{(z_1, \ldots, z_n) \in \overline{\mathbb{D}^n}} | p (z_1, \ldots, z_n) |$$ I've heard numerous anecdotes from professors and other scientific employees, that there has been some more recent results in this field. One of them being "using graph theory for $n \ge 3$", and the other one "using spectral theory". I couldn't find anything new, the only "newest" thing is Shalit's work from 2021 if I remember correctly. Could anyone help me out?

5n+1 sequence starting at 7

Consider the following variant of the Collatz function: $f:\mathbb N\rightarrow\mathbb N$ is defined by \begin{equation} f(n):=\begin{cases} n/2 & \text{if n is even}\\ 5n+1 & \text{if n is odd}\\ \end{cases} \end{equation} Contrary to the Collatz function with $3n+1$, many orbits of this function seem to diverge. The smallest one is probably 7. After 32282 iterations, $f^k(7)$ is already larger than 10^{1000}. Can one prove that this orbit diverges to infinity? Here is the Python code that I used: from decimal import * getcontext().prec=1001 def collatz5(n): if n%2 == 0: return Decimal(n)/Decimal(2) else: return Decimal(5)*Decimal(n)+Decimal(1) n=7 for i in range(100000): if n>10**1000: print("bound exceeded") print("number of steps: ",i) break n=collatz5(n)

Optimal covering trails for every k-dimensional cubic lattice $\mathbb{N}^k := \{(x_1, x_2, \dots, x_n) : x_i \in \mathbb{N} \wedge n \geq 3\}$

After a dozen years spent investigating this particular class of problems, I finally give up and I wish to ask you if any improvement is achievable from here on. The general problem is as follows: Let the k-dimensional grid $\mathcal{H}(n,k):=\{0,1,2,\ldots,n-1\} \times \cdots \times \{0,1,2,\ldots,n-1\}$ be given in the Euclidean space $\mathbb{R}^k$. How many line segments connected at their endpoints have the minimum-link covering trails that join all the points of $\mathcal{H}(n,k)$ (i.e., the optimal polygonal chain that visits all the given n^k points by spending the minimum number of line segments)? Then, let us call $h(n,k)$ the mentioned minimum number of links. Accordingly, let us denote with $h_l(n,k)$ the proven lower bound for $h(n,k)$ and with $h_u(n,k)$ the corresponding upper bound so that we can state the following set of relations. \begin{equation} h(n,1)=1, \forall n. \end{equation} \begin{equation} h(n,2)=2 \cdot (n-1), \forall n \geq 3. \end{equation} \begin{equation} h(1,k)=1, \forall k. \end{equation} \begin{equation} h(2,k)=3 \cdot 2^{k-2}, \forall k \geq 2. \end{equation} \begin{equation} h(3,k)=\frac{3^k-1}{2}, \forall k. \end{equation} \begin{equation} h(n,k) \leq \Bigg(\Bigl\lfloor{\frac{3}{2} \cdot n^2}\Bigl\rfloor - \Bigl\lfloor{\frac{n-1}{4}}\Bigl\rfloor + \Bigl\lfloor{\frac{n+1}{4}}\Bigl\rfloor - \Bigl\lfloor{\frac{n+2}{4}}\Bigl\rfloor + \Bigl\lfloor{\frac{n}{4}}\Bigr\rfloor + n - 1 \Bigg) \cdot n^{k-3} - 1, \forall n\geq 3 \wedge \forall k \geq 3 \end{equation} \begin{equation} h(n,k) \geq \frac{n^k-1}{n-1}, \forall n \geq 3 \wedge \forall k. \end{equation} \begin{equation} h(n,k) \leq (h_u(n,3)+1) \cdot n^{k-3}-1, \forall n\geq 3 \wedge \forall k \geq 3. \end{equation} Thus, what I have currently found is resumed in the table below, where the strictly proven results are highlighted in the green cells, while the proven bounds are shown in the orange cells. $\{0,1,2,\dots,n-1\}\times\{0,1,2,\dots,n-1\}\times \dots \times\{0,1,2,\dots,n-1\}$ points problem in $\mathbb{R}^k$." /> Conjecture: $h(n,k)=\frac{n^k-1}{n-1}+c \cdot (n-3)$, where $c = k-1$ iff $h(4,3)=23$, $c = 1$ iff $h(4,3)=22$, or even $c = 0$ iff $h(4,3)=21$ (see also this Previous discussion about finding the value of $h(4,3)$). Any idea to go further (can we see some kind of pattern in the table)? Thanks in advance!

A more complete set of open problems

Over time, there have been a number of posts on open problems remaining in different fields of math, both here and on the MathSE. So I had the idea of trying to construct a “list of lists” of problems from the many that exist - and it turns out someone else has already started such an effort! I’ve found something quite neat, so I’ll be posting an answer below.

Open problems which might benefit from computational experiments

Question: I wonder what are the open problems , where computational experiments might be helpful? (Setting some bounds, excluding some cases, shaping some expectations). Grant program: The context of the question is the following - in some sense there is a way to crowdsource some (quite specific, but still) computational experiments - the platform for data science challenges Kaggle (Google's subsidiary) - offers grants to researchers in various fields to organize the challenges. Properly organized it might attract thousands of participants, some of whom are extremely skilled in solving computational challenges (like NVIDIA grandmaster's team - 6 super-skillful guys who are paid by NVIDIA just to participate in challenges (and promote some NVIDIA tools) - kind of profi-sportsmen). There already

many research oriented challenges took place - mainly around in bioinformatics (e.g. CAFA5, Stanford-Ribonanza, Single Cell Perturbations, etc..). Example: The one quite related to mathematics - is ongoing challenge on finite permutation groups - the task is to find as short paths as possible for sets of given points on Cayley graphs. The groups include N-dimensional Rubik's cube and other puzzle motivated groups like "Globe". For example even the diameters of the N-dimensional Rubik's cube are still unknown, so computational experiments may shed light on these questions. The other questions - like better understanding of the random walks, growth patterns, patterns of mixing, fast scrambling algorithms - seems to be of interest from both sides - machine learning and mathematical. So fruitful idea exchanges and interconnections might be possible. It would be great if some mathoverflow colleagues experienced in such kind of permutation group questions may share experience - please post on forum e.g. here or/and contact e.g. me. PS I am a kind of a fan of many sides of Kaggle - it managed to create a community of people who are not only competing but sharing lots of experience. Gamified "reputation" scores - similar to mathoverflow - play a role, moreover Kaggle rankings are appreciated in the data science world, so can help to find a better job - another stimulus for many to participate, in addition to networking. Many people think that the best way to learn practical data science - participate in Kaggle challenges. It is not only for competition, but a free cloud service - like Google Colab, but more devoted to team work - offering free computing power, storage, sharing, version control, team work. Would be great to have something similar for mathematical community or to use Kaggle itself for mathematical community - one may think of a competition as a kind of mini-"Polymath" project. Where all the infrastructure - is ready - forum, community, free computing power - the only thing one needs - is to create a challenge. Kaggle offers everybody to create a challenge for free, but only "official" challenges attract most attention.

Squares whose differences are squares

EDIT. I've just noticed a thread from 2011 in the "Related" column on the right (click me), where a closely related question is being discussed (the main difference seems to be that, in Question 2 below, I'm only asking for the existence of an upper bound). A subproblem of Problem D18 in the 2004 softcover reprint of the 3rd edition of Guy's Unsolved Problems in Number Theory asks if there are four squares the absolute values of whose differences in pairs are squares (see p. 278 in the book, the subproblem is titled "Four squares whose differences are square"). Guy comments that "Although a solution is unlikely, there do not appear to be any congruence conditions which forbid it." I have two (main) questions: (Q1) What is the status of the problem? Has there been any substantial progress since 2004? (Q2) What about the existence of an integer $N \ge 4$ such that there is no N-tuple $(a_1, \ldots, a_N)$ of positive integers with the property that $|a_i^2 - a_j^2|$ is a square for all $i, j = 1, \ldots, N$? More precisely, what about $N = 5$? The question is motivated by a problem in graph theory posed by Sergey Goryainov. I'm mainly looking for references.

Natural numbers n which satisfy gnu(n)=n?

Are there any natural numbers n (other than 1) for which $gnu(n)=n$? We define $gnu(n)$ to be the number of isomorphism classes of groups of order n. This question popped into my head today, and I couldn't come up with a proof one way or another. In the paper by Conway, et al. entitled "Counting Groups: Gnus, Moas, and other Exotica, Conjecture 10.1 implies that there should be no such natural number n which satisfies $gnu(n)=n$. Does anybody have an argument to show that there is no natural number n (other than 1) for which $gnu(n)=n$? If it is really straightforward, just say so and I'll work it out for myself when I find time. Thanks!

Zeroes of a tricky function.

I am attempting to show that there does not exist an N past which every open unit interval (k, k+1) -where k is an integer- contains a zero of the following function: $h(x)=\sum_{n=2}^{[\sqrt(x)]} \frac{\cot(x\pi/n)}{n}+\frac{\cot((x+2)\pi/n)}{n}$ Where the $[\sqrt(x)]$ is the lowest integer of the square root of x. Any thoughts? I had figured that I could consider the interval $(i^2, (i+1)^2)$ in which h(x) is described by the function $h(x)=h_n(x)=\sum_{n=2}^{i} \frac{\cot(x\pi/n)}{n}+\frac{\cot((x+2)\pi/n)}{n}$ Then try to see on what unit intervals (k, k+1) in here contain a zero of h_n then try to show that $((i+1)^2, (i+2)^2)$ also has such an interval, but I am running out of ideas.

On the number of complete Boolean algebras

In their 1972 paper On the number of complete Boolean algebras Monk and Solovay showed that if λ is an infinite cardinal, then there are 2^{2^λ} many isomorphism types of complete Boolean algebras of power $2^\lambda.$ On the other hand, by a result of Pierce, a complete Boolean algebra of infinite power κ exists iff $\kappa=\kappa^{\aleph_0}$. In the above mentioned paper, the following is asked: Question. Suppose $\kappa=\kappa^{\aleph_0}$, but it is not of the form 2^λ for any λ. Are there ${2^\kappa}$ many isomorphism types of complete Boolean algebras of power $\kappa?$ What is known about the above question?

level sets of multivariate polynomials

Let $p:\mathbb R^n \rightarrow \mathbb R$ be a polynomial of degree at most d. Restrict p to the unit cube $Q=[0,1]^n\subset\mathbb R^n$. We assume that p has mean value zero on the unit cube Q: $$\int_Q p(x) dx = 0.$$ For $\alpha>0$ consider the sublevel sets of P, $$E_\alpha= \{x\in Q: |p(x)|\leq \alpha\}$$ There are several known estimates for the Lebesgue measure of this set which in some sense or another are uniform over some classes of polynomials. For example, we have that $$|E_\alpha| \lesssim \min(pd,n) \frac{ \alpha^{1/d} }{ \|p\|_{ L^p(Q) }^{1/d} } $$ This particular estimate is due to Carbery and Wright and can be found here. I'm interested in studying the (induced Lebesgue) measure of the boundary of this set $$|\partial E_\alpha|=|\{x\in Q: |P(x)|=\alpha\}| $$ Consider first the easy case of dimension $n=1$. Then the set E_α is a finite union of closed intervals and the question is trivial. It is obvious that in this case there are at most $O(d)$ intervals so the 0-dimensional measure of the boundary is $O(d)$. Now in many variables things will be much more complicated. For example can we say that the set E_α has $O(d)$ connected components? Is there an estimate for the measure of the boundary $\partial E_\alpha $ in terms of α, d and n, assuming (say) that $\|p\| _ {L^1(Q)}=1$? This question comes up naturally if one tries to study an oscillatory integral with phase p and apply integration by parts (i.e Gauss theorem) imitating the one dimensional method of proving the van der Corput lemma (for example).

Covering the primes by arithmetic progressions

Define the length of a set of arithmetic progressions of natural numbers $A=\lbrace A_1, A_2, \ldots \rbrace$ to be $\min_i | A_i |$: the length of the shortest sequence among all the progressions. Say that A exactly covers a set S if $\bigcup_i A_i = S$. Let P' be the primes excluding 2. What is the longest set of arithmetic progressions that exactly covers the primes P'? In other words, I want to maximize the length of a set of such arithmetic progressions. Call this maximum $L_{\max}$. $L_{\max} \ge 2$ because $$ P' \;=\; \lbrace 3,5 \rbrace \cup \lbrace 7,11 \rbrace \cup \cdots \cup \lbrace 521,523 \rbrace \cup \cdots $$ Perhaps it is possible that $$P' \;=\; \lbrace 3, 11, 19 \rbrace \cup \lbrace 5, 17, 29,41,53 \rbrace \cup \lbrace 7,19,31,43 \rbrace \cup \cdots \;,$$ but I cannot get far with sequences of length ≥ 3. (I know Green-Tao establishes that there are arbitrarily long arithmetic progressions in P, but I don't know if that helps with my question.) I am number-theoretically naïve, and apologize if this question is nonsensical or trivial. In any case, I appreciate the tutoring! Addendum. Although my question should be revised (as Idoneal suggests) in light of George Lowther's proof that 3 cannot be in a progression of length 4, George has shown that it is likely that $L_{\max}=3$ but certification requires resolving an open problem. So I've added the open-problem tag. Thanks for everyone's interest!

Could I possibly exploit distinct odd primes raised to 6 to solve Exact Three Cover, when reducing it in Subset Sum?

I'm solving Exact 3 Cover, given a list with no duplicates S of $3m$ whole numbers and a collection C of subsets of S, each containing exactly three elements. The goal is to decide if there are $\operatorname{len}(S)/3$ subsets that cover every element in S one time. N is the $len(S)$ I'm going to use Subset Sum to solve Exact 3 Cover. I reduce Exact Three Cover into Subset Sum by transforming S into N odd distinct primes raised to 6, and easily map out the collection of subsets in the same manner. I then get the sums of the transformed collection of subsets. And the sum of the transformed S will be our target sum. So now I have a transformed $S = {p_1^6, p_2^6, p_3^6...}$ into the first N distinct odd primes raised to 6. There are rules for combinations of size three to ensure distinctness. All combinations of size three must be sorted in ascending order. There will be no duplicate subsets. There will be no subsets that have elements not in S . There will be no subsets that have duplicate elements. This does not affect correctness, as it is either impossible or not necessary that a solution could use these subsets. We easily filter the input to get rid of these unnecessary subsets. The conjecture is that no distinct subset that was transformed into primes raised to 6 could have duplicate sums. Because duplicates could cause collision and the reduction would fail. This is a variant of the unsolved problem of $a^6 + b^6 + c^6 ≠ d^6 + e^6 + f^6$ where variables are distinct primes. In this case both sides of the equation is supposed to be distinct subsets of size three. Of course, we have to tweak it to encapsulate all combinations of size 3. For example, When a variable is shared between two distinct subsets. $A^6 + b^6 + c^6 ≠ A^6 + e^6 + f^6$ $b^6 + c^6 ≠ e^6 + f^6$ is another open problem for distinct primes, it also implies $A^6 + b^6 + c^6 ≠ A^6 + e^6 + f^6$ When two variables are shared between two distinct subsets. $A^6 + B^6 + c^6 ≠ A^6 + B^6 + f^6$. What about when two subsets share all variables? Per the rules of combinations no duplicate subsets. Because $a^6 + b^6 + c^6 = a^6 + b^6 + c^6$ For generality the position of shared variables could be at any location on either side of the equation. Also the unique factorization of each p^6 seems to imply unique sums for all combinations of size 3. My question is, could I possibly exploit properties of numbers to solve Exact Three Cover more efficiently? Everybody's looking to use conventional techniques to solve NP complete problems, but nobody seems to looking for how numbers work. And, I think that could yield interesting finds. Even if the reduction is dependent on conjecture, its still nonetheless interesting. I have written code for empirical analysis, and I've had no duplicate sums all the way up to 500. This was originally asked on Theoretical Computer Science

Congruence obstructions for three consecutive powerful numbers

A powerful number is an integer m such that if p is prime and $p \mid m$ then $p^2 \mid m$. Powerful numbers can be represented in the form $m=u^2 v^3$. Erdos conjectured that three consecutive powerful numbers don't exist. Assume $(a-1,a,a+1)$ is a

triple of consecutive powerful numbers. Choose integers n,A and set $a=A$ and assume the system $$x_1^2 x_2^3=A-1, y_1^2 y_2^3=A+1$$ doesn't have solution modulo n. Then over the integers powerful triple with $a \equiv A \pmod{n}$ doesn't exist. Some examples with n square: n | A congruence obstruction 4 [1, 3] 9 [2, 4, 5, 7] 16 [1, 3, 5, 7, 9, 11, 13, 15] 25 [4, 6, 9, 11, 14, 16, 19, 21] 36 [1, 2, 3, 4, 5, 7, 9, 11, 13, 14, 15, 16, 17, 19, 20, 21, 22, 23, 25, 27, 29, 31, 32, 33, 34, 35] 49 [6, 8, 13, 15, 20, 22, 27, 29, 34, 36, 41, 43] Q1 Can we find n and congruence obstructions to show non-existence of more naturally defined powerful triples? Q2 Can we show that for some even B the triple with $a=B^k$ doesn't exist for all k? (For odd B this is visible with naked eye)

No starter "accessible" well known open problems

We all know very famous open problems. Usually the ones that become famous are well studied and lots of progress was achieved and conjectures, partial results, reductions and so on exist. This is one of the reasons they become famous. This kind of problems are usually hopeless to attack without lots of investment of time and dedication to learn the basics and beyond. I am interested in the other extreme, that is, I would like relatively easy to state problems which are well known (at least in the relevant area), but no one has a clue how to start solving them, preferably no one even has a good guess what the right answer is. Let me give you two examples from my research area: A pro-p group in which there exists a bound on the number of generators (topologically) for all closed subgroups is said to have finite rank. These are well known due to the works of Lazard, and Lubtozky and Mann, for instance, they are p-adic analytic. However, as far as I know known no-one has a clue whether a pro-p group in which every closed subgroup is finitely generated has finite rank? In other words, if a pro-p group is not of finite rank does it contain a closed subgroup which is not finitely generated? Zelmanov solved the Restricted Burnside Problem that is there are finitely many finite p-groups with d-generators and exponent at most e. This is equivalent to saying that every finitely generated pro-p of finite exponent is finite. He also generalized and proved the Burnside Problem for pro-p groups, that is, every finitely generated torsion pro-p is finite. However, the Generalized Burnside Problem for pro-p group is completely open, that is, is it true that a torsion pro-p group (not necessarily f.g.) has finite exponent? (I'll just comment that Burnside kind of problems are usually very hard.) Motivation: Well I recently retired and while I do not have the energy (or talent) to try to solve most famous open problem, it would be nice to have a list of famous problems that either by luck one might encounter a counter example or by luck one might find a very different approach.

A probability involving areas in a random pentagram inscribed in a circle: Is it really just $\frac12$?

This question was posted at MSE but was not answered. The vertices of a pentagram are five uniformly random points on a circle. The areas of three consecutive triangular "petals" are a,b,c. The petals are randomly chosen, but they must be consecutive, either clockwise or anticlockwise. A simulation of 10^7 such random pentagrams yielded a proportion of 0.5000179 satisfying $a^2<bc$. Is the following conjecture true: $P(a^2<bc)=\frac{1}{2}$ Remarks Note that the three petals must be consecutive. Calling the areas of consecutive petals a,b,c,d,e, simulations suggest that: $P(a^2<bd)\approx0.468$ $P(a^2<be)\approx0.505$ $P(a^2<cd)\approx0.460$ Curiously, the probability that seems to equal $\frac{1}{2}$, i.e. $P(a^2<bc)$, does not involve a symmetrical arrangement of three petals. As for other random star polygons $\{\frac{n}{2}\}$ inscribed in a circle, simulations suggest that Star polygon $\left\{\frac{6}{2}\right\}$: $P(a^2<bc)\approx0.505$. Star polygon $\{\frac{7}{2}\}$: $P(a^2<bc)\approx0.504$. I used the shoelace formula to calculate the areas of the triangular petals. One might expect that a probability of $\frac12$ should have an intuitive explanation, but sometimes probabilities of $\frac12$ are hard to explain. Underlying reason? Simulations suggest that the random pentagram/pentagon shape is teeming with probabilities of powers of $\frac12$. In the following diagram, the letters represent areas of the regions. $P(g+b+h<a+f+c)\overset{?}{=}\color{red}{\frac{1}{2}}$ $P(g+h<f)\overset{?}{=}\color{red}{\frac{1}{4}}$ $P((g+a+k)(h+c+i)>(b+f+e+d+j)^2)\overset{?}{=}\color{red}{\frac{1}{8}}$ $P(\text{each region with area g,b,f,l contains the centre of the circle})=\color{red}{\frac{1}{16}}$ (proved) $P(\text{areas of petals increase going around once, clockwise or anticlockwise})\overset{?}{=}\color{red}{\frac{1}{32}}$ I am not asking to prove these other probability claims. I am presenting them to suggest that there may be an underlying reason why the pentagram has probabilities of powers of $\frac12$, which may be relevant to my conjecture. These simulations make me more inclined to believe that my conjecture is true, but I could be wrong.

Probability of finding a prime number between $x-\ln(x)$ and $x+\ln(x)$

Using my computer, I found that in the interval $[1, N]$ the probability of finding a prime number between $x-\ln(x)$ and $x+\ln(x)$ is greater than constant c where $N=10^2, 10^3,...,10^{9}$, x is the positive integer number in $[1, N]$ and $c > 0.8$. Question: Does the result hold for $N \to +\infty $?

Conjecture: x^4+1 is never Wieferich prime

Related to this question and Alexander Kalmynin's answer. For natural n define $J(n)=(2^{n-1}-1) \bmod n^2$ and if n is power of two define $J(2^n)=1$ (this is artificial, just to avoid triviality and by $\bmod$ we mean take the smallest residue modulo n^2). Prime p is Wieferich prime iff $J(p)=0$. The answer in the linked question use the doubly exponential sequence of Fermat numbers and we are trying to generalize this. Conjecture 1: For even n we have $J(n^2+1) < J(n^4+1)$ and hence $J(n^4+1)>0$, so n^4+1 can't be Wieferich prime. This holds for n up to 10^6 and several very large n. Further we have: Conjecture 2 For even n large enough we have $\frac{\log(J(n^4+1))}{\log{J(n^2+1)}} \sim 2$. Q1 If Conjecture 1 is false, can we use this approach to show primes of certain form are not Wieferich?

Open problems in complete theories

It is well-known that every complete recursively enumerable first-order theory is decidable. Does that mean that such theories are "trivial", or are there still interesting open problems that we potentially know the answer of (by running a computer for an (insane) amount of time)? Examples of complete theories include: Presburger arithmetic Tarski's axioms for Euclidean geometry The theory of dense linear orders without endpoints The theory of algebraically closed fields of a given characteristic The theory of real closed fields Most (all?) examples given here about Euclidean geometry do not seem to be expressible in Tarski's language.

Does the sequence formed by Intersecting angle bisector in a pentagon converge?

I asked this question on MSE here. Given a non-regular pentagon $A_1B_1C_1D_1E_1$ with no two adjacent angle having a sum of 360 degrees, from the pentagon $A_nB_nC_nD_nE_n$ construct the pentagon $A_{n+1}B_{n+1}C_{n+1}D_{n+1}E_{n+1}$ as follows: A_{n+1} is the intersection between the angle bisectors of $\angle C_n $ and $\angle D_n$. B_{n+1} is the intersection between the angle bisectors of $\angle D_n$ and $\angle E_n$. C_{n+1} is the intersection between the angle bisectors of $\angle E_n$ and $\angle A_n$. D_{n+1} is the intersection between the angle bisectors of $\angle A_n$ and $\angle B_n$. E_{n+1} is the intersection between the angle bisectors of $\angle B_n$ and $\angle C_n$. (the intersection of the angle bisectors of the two opposite angles) I am allowing self-intersecting polygons in this constructions. The reason why I chose this construction is that the point A_{n+1} is the only point that doesn't depend on A_n. My question is if this process is repeated indefinitely would the sequences ${A_n}$, ${B_n}$, ${C_n}$, $D_n $ and E_n converge ? and if they converge what is the limit? if they din't always converge what are the necessary conditions that the pentagon $A_1B_1C_1D_1E_1$ should satisfy so the five sequences converge ? There are only four possible scenarios: The points will converge. The points will eventually trapped on a loop. The points will diverge completely. Two or more points coincide, or two adjacent angle have a sum of 360 degrees ending the sequence. I tried to draw the first few pentagons to see if the point will converge or not. Here is the first 50 pentagons in a zoom-in animation: I conjecture that the sequences converge to a single point for all non-regular pentagons. If convergence occurs, how can we determine the limit point based on the initial pentagon? If the limit point exist what interesting properties does it have for the pentagon? Here is a Geogebra file that have the first 50 pentagons. I wrote a python code than can calculate A_n, B_n , C_n ,D_n ,E_n given the initial pentagon: import math print("Number of pentagons") n=int(input()) m=max(n,50) from decimal import Decimal import decimal decimal.getcontext().prec = m Decimal(10)**(-m) # enter your coordinates here A=[Decimal(0),Decimal(0)] B=[Decimal(0),Decimal(0)] C=[Decimal(0),Decimal(0)] D=[Decimal(0),Decimal(0)] E=[Decimal(0),Decimal(0)] print("Enter the coordinates of A_1") A[0]=Decimal(float (input())) A[1]=Decimal(float (input())) print("Enter the coordinates of B_1") B[0]=Decimal(float (input())) B[1]=Decimal(float (input())) print("Enter the coordinates of C_1") C[0]=Decimal(float (input())) C[1]=Decimal(float (input())) print("Enter the coordinates of D_1") D[0]=Decimal(float (input())) D[1]=Decimal(float (input())) print("Enter the coordinates of E_1") E[0]=Decimal(float (input())) E[1]=Decimal(float (input())) X=[Decimal(0),Decimal(0)] Y=[Decimal(0),Decimal(0)] Z=[Decimal(0),Decimal(0)] W=[Decimal(0),Decimal(0)] T=[Decimal(0),Decimal(0)] #defining some useful functions---------- def v(a,b): result= [b[0]-a[0], b[1]-a[1]] return result def crs(a, b): result = [-Decimal(0.5)*((Decimal(a[0]*b[1])-Decimal(a[1]*b[0])))] return result def dis(a,b): result =[Decimal(math.sqrt((a[0]-b[0])**2+(a[1]-b[1])**2))] return result for i in range (2,n+1): AB= dis(A,B)[0] BC= dis(B,C)[0] CD= dis(C,D)[0] DE= dis(D,E)[0] EA=

Difficult examples for Frankl's union-closed conjecture

Frankl's well-known union-closed conjecture states that if F is a finite family of sets that is closed under taking unions (that is, if A and B belong to the family then so does $A\cup B$), then there must be an element that belongs to at least half the sets. I know that pretty well any naive approach one takes to this conjecture is known to fail. By "naive approach" I suppose I mean something like an observation that it would follow from such-and-such a stronger conjecture -- it seems that all sensible stronger conjectures one thinks of are false. A very simple example of a stronger conjecture would be that if you pick a random element then on average it will belong to at least half the sets. That is completely false: take the family that consists of the empty set, {1}, and {1,2,3,4,5,6,7,8,9,10}, for example. One can try to "correct" this strengthening by devices such as insisting that for any two elements there is a set that contains one and not the other (which WLOG is the case), but such corrections don't get one very far. What I am asking for is examples, either small ones or ones that are constructed theoretically, of union-closed families that defeat more sophisticated strengthenings of the original conjecture. I'm fairly sure they are out there but I am not an expert on this problem so I don't know them myself. Apologies in advance if this resembles an existing question (which it feels as thought it easily might). But I've looked and not found anything.

A generalization of Barrow's inequality

More than seven years ago. I posted this problem in stackexchange: Let ABC be a triangle, P be arbitrary point inside of ABC. Let $A_1B_1C_1$ be the tangential traingle of ABC. Let A', B', C' be three be arbitrary points on B_1C_1, C_1A_1, A_1B_1 respectively. Let internal angle bisectors of three angles $\angle B'PC'$, $\angle C'PA'$, $\angle A'PC'$ meet BC, CA, AB at A'', B'', C'' respectively. Then $$PA'+PB'+PC' \ge 2(PA''+PB''+PC'')$$. Equality hold iff ABC be an equilateral triangle and $\angle B'PC'= \angle C'PA'=\angle A'PC' =120^0$ When $A' \equiv A, B' \equiv B, C' \equiv C$ we have Barrow's inequality I am looking for a proof the conjecture. See also: Erdős-Mordell inequality Barrow's inequality

Open problems in differential algebra and affine algebraic geometry

I am currently doing a PhD in differential algebra and affine algebraic geometry at the University of Buenos Aires. I've been struggling to find a list of interesting and big open problems in these areas. I would be interested in a list of problems or also a list of subtopics that are currently on trend together with a list of reasons about their importance/influence in the area.

Papers showing two open problems are connected

I'm currently writing an article in which I connect two open problems from different fields of mathematics (group theory and combinatorics). While writing the introduction, I was trying to think of other examples of two problems from different fields of mathematics that are connected. I could only think of the modularity theorem (formerly known as the Taniyama-Shimura-Weil conjecture) and Fermat's Last Theorem. Both are now solved, but historically, it was first shown that they are related; more specifically, that a negative answer to Fermat's Last Theorem would yield a negative answer to the Taniyama-Shimura-Weil conjecture. My question is: What are other examples of such connections? Edit: based on coLaidernotte's suggestion, the type of connections I'm looking for can better be described as follows: examples of two (or more) open problems that are not considered related at first, but which are eventually proved in a uniform way or proved to be closely related.

Solving functional analysis problems by using Algebraic geometry

I am thinking about some open problems in nonlinear functional analysis and I just wanted to know if there are any problems that have been solved by using Algebraic geometry techniques in these fields.

Poisson binomial conjecture

Let $X_i\in\{0,1\}$ be mutually independent and distributed according to $\mathrm{Bernoulli}(p_i)$ and similarly, $Y_i\sim\mathrm{Bernoulli}(q_i)$, for some parameters $p,q\in[0,1]^n$. Put $X:=\sum_{i=1}^n X_i$ and $Y:=\sum_{i=1}^n Y_i$; both take values in $\{0,\ldots,n\}$. Assume $p_i\ge q_i$ and even n, put $\gamma:=\frac1n\sum_{i=1}^n(p_i-q_i)$, and let $\bar X\sim\mathrm{Binomial}(n,1/2+\gamma/2)$ and $\bar Y\sim\mathrm{Binomial}(n,1/2-\gamma/2)$. Conjecture: $$\max_{k\ge 0} | \mathbb{P}(X\ge k) - \mathbb{P}(Y\ge k) | \ge \mathbb{P}(\bar X\ge n/2) - \mathbb{P}(\bar Y\ge n/2) .$$ This would imply, in particular, a positive resolution of the conjecture in Minimizing total variation under constraint

Artin's conjecture for $n=2$

I am interested in the following question: Is it known that 2 is a primitive root modulo p for infinitely many primes p? There is some information about Artin's conjecture in Wikipedia. I need to know if it is up-to-date and if one can say something about the case $n=2$.

Have the open Questions 1 and 2 from Section 7 of the paper "Integrals with values in Banach spaces" been answered?

Some context: I had previously asked the post below on MSE, but someone suggested I ask it here and delete the original post. In section 7 of the paper Integrals with values in Banach Spaces and locally convex spaces by Piotr Mikusiński (2014), two open questions are presented: Question 1: If $f: X \to E$ (where E is a complete locally convex space) and $\pi_\alpha f$ (where $\{|\cdot|\}_\alpha$ is a family of seminorms for the topology of E and π_α the projection from E to the quotient normed space E_α) is Bochner integrable for every $\alpha \in I$, is f integrable? Question 2: Is the space $L^1(X, \mu, E)$, which consists of E-valued functions that are integrable with respect to a measure μ on X, complete under the topology induced by the family of semi-norms $|\cdot|_\alpha$? Have these questions been answered since the paper was written? Any updates or references would be appreciated.

Are local complete intersections of small codimension necessarily (global) complete intersections?

Hartshorne's 1974 conjecture states that a smooth closed subvariety X of $\mathbb{CP}^r$ of dimension $>2/3r$ is necessarily (globally) a complete intersection. Is anything interesting known about this conjecture? Can it (maybe, in a weaker form) be true if one only assumes X to be a local (set-theoretic) complete intersection? If any counterexamples (that is, local set-theoretic complete intersections of small codimension that are not complete intersections) are known, I would like to know their lower cohomology.

A new Conjecture at OEIS sequence A376842

Here is a new conjecture of mine from the appendix of an unpublished manuscript currently under review. Let $b \in \mathbb{Z}^+$ and assume that n is an integer greater than 1 and not a multiple of 10. Let $^b{n}$ be $n^{n^{{\cdots}^n}}$ (b-times $-$ see tetration). Then, let us call $\bar{b}$ the smallest hyperexponent of n such that the congruence speed of n is constant (i.e., $\bar{b} := \bar{b}(n)$) and matches the result of Equation (16) of This Paper. Finally, in radix-10, we define as asymptotic phase shift of n (APH(n)) the n-th term of the OEIS sequence A376842 (i.e., A376842(n)), where, if n is not a multiple of 10, the value of the most significant digit of each A376842(n) corresponds to the congruence class modulo 10 of the difference between the rightmost non-stable digit of $^\bar{b}{n}$, say the m-th by counting digits from right to left, and the m-th rightmost digit of $^{\bar{b}+1}{n}$ (which is always a stable digit since the constant congruence speed of n necessarily belongs to $\mathbb{Z}^+$). E.g., if $n =

57$ is given, then we calculate APS(57) by looking at the following sequence of iterations: $\ldots 00000000000000000000000000057$ (height $b = 1$), $\ldots 860230813777543677048556880 57$ (height $b = 2$), $\ldots 443464175207610790048796880 57$ (height $b = 3$), $\ldots 666446504611015011568796880 57$ (height $b = 4$), $\ldots 671511645122477971568796880 57$ (height $b = 5$), $\ldots 190953270434557971568796880 57$ (height $b = 6$), $\ldots 328651320274557971568796880 57$ (height $b = 7$), $\ldots 933653640274557971568796880 57$ (height $b = 8$), $\ldots$ Since the constant congruence speed of 57 is 3 and $\bar{b}(57)=1$, we can finally state that APS$(57) = 2684 = A376842(57)$. Question: Does the following conjecture hold for every $n \in \mathbb{N}-\{1\} : n \not\equiv 0 \pmod{10}$? Conjecture: For any given $n \in \mathbb{N}-\{1\} : n \not\equiv 0 \pmod{10}$, A376842$(n) \in$ $\{2, 4, 5, 6, 8, 9, 19, 28, 46, 64, 82, 1397, 1793, 2486, 2684, 3971, 4268, 4862, 6248, 6842, 7931, 8426, 8624\}.$ Note that each term of the set $\{2, 4, 5, 6, 8, 9, 19, 28, 46, 64, 82, 1397, 1793, 2486, 2684, 3971, 4268, 4862, 6248, 6842, 7931, 8426, 8624\}$ corresponds to some value of n (a direct proof is included in Section 3 of the mentioned manuscript). Moreover, if $2 \mid n$ or $5 \mid n$ (and $n \neq 5$) we have that $\bar{b}$ does not exceed 3 while APS$(n) \not\in \{9,19,1397,1793,3971,7931,\}$.

A Game of Knights and Queens

Let $m,n,u,v \in \mathbb{N}$ be parameters with $m,n \geq 3$. Suppose two players play a game on a $m \times n$ chess board and we denote the squares of the board by the set of points $ (i,j) $ such that $1 \leq i \leq m, 1 \leq j \leq n $. Player 1 has u queens, and player 2 has v knights. The initial configuration is some given subset of the board where no piece is placed at a position that can be immediately attacked by another piece of the opposing player, and the player with at least one piece when the game terminates is the winner. Both players must make a move when it is their turn. The game terminates when either player captures all of the pieces of the opposing player. If Player 1 goes first, under what circumstances does either player have a winning strategy? What can be said about the probability as a function of the parameters given with both players playing optimally, that the game will terminate in finitely many steps? I have obtained the result for $m = 3$ and arbitrary n with $u= v = 1$. Ed Dean proved that Player 1 always has a winning strategy for arbitrary m,n and $u = v = 1$ (see below), and he sketched a winning strategy for Player 1 in the $u = 1, v = 2$ case. He also gave an argument for the lack of a winning strategy for Player 1 for the $u = 1, v = 3$ case. All other cases are still unknown as of yet. Edit: Previous suggestion on a way to show in the $u = v = 1$ case that the knight can avoid capture for sufficiently large m,n is removed. Edit 2: Thanks to Ed Dean for resolving some cases, as indicated above. Edit 3: Included a new question regarding a related probability distribution. Edit 4: Moved edit 3 to a new question: A random variable in a game of knights and queens

Does a matrix ring over a ring satisfy the Koethe conjecture if the coefficient ring itself satisfies the Koethe conjecture?

I just want to know whether the following statement is true or false. If R is a ring satisfying the Koethe conjecture, then the matrix ring over R also satisfies the Koethe conjecture. Or is it equivalent to the Koethe conjecture itself? I will be grateful if you can link to a paper or a book.

On Sorli's Conjecture Re: OPNs (Circa 2003)

In the PhD dissertation titled "Algorithms in the Study of Multiperfect and Odd Perfect Numbers" (hyperlinked here) and completed in 2003, Ronald Sorli conjectured that the exponent k on the Euler prime p for an odd perfect number $N = (p^k)(m^2)$ is one (i.e. we can drop k). Assuming Sorli's conjecture is true, does anyone know if there exist (any) "effective" results (pardon my use of the term, I just could not think of a better word) in the literature, particularly with respect to relations between the Euler prime p, the exponent k and the number $\sqrt{\frac{N}{p^k}}$? I have, so far, only been able to get hold of Paolo Starni's article titled "Odd Perfect Numbers: A Divisor Related to the Euler's Factor". In particular, note that Sorli's conjecture implies the following relations: $$I(p^k) = I(p) = \frac{p+1}{p}$$ $$I(m^2) = \frac{2}{I(p)} = \frac{2p}{p + 1}$$ which, in turn, gives the (trivial) algebraic identity: $$\frac{1}{p} = \frac{1}{p+1} + \frac{1}{p}\left(\frac{1}{p+1}\right)$$ where p is the Euler prime (i.e. p^k is the Euler's Factor) and $$I(x) = \frac{\sigma(x)}{x}$$ is the abundancy index of x. [Edit (September 18 2013) - Per Professor Beasley's paper titled "Euler and the Ongoing Search for Odd Perfect Numbers" from this hyperlink: Before proceeding with Euler's proof, we pause to note that his result was not quite what Descartes and Frenicle had conjectured, as they believed that $k = 1$, but it came very close. In fact, current research continues in an effort to prove $k = 1$. For example, Dris has made progress in this direction, although his paper refers to Descartes' and Frenicle's claim (that $k = 1$) as Sorli's conjecture; Dickson has documented Descartes's conjecture as occurring in a letter to Marin Mersenne in 1638, with Frenicle's subsequent observation occurring in 1657. End Edit.]

Reference Request - Sharp Estimates for a Logarithmic Sum

Can anybody suggest a good (e.g. "non-technical") introduction to estimating bounds for logarithmic sums of the form $$\sum_{i=1}^{r}{{\alpha_i}{\log(q_i)}}$$ where the $$\alpha_i$$ are positive integers (not necessarily distinct) and the $$q_i$$ are odd primes?

The reason why I ask this question is because I am trying to estimate (both lower and upper) bounds for the logarithm of a number-theoretic function, specifically $$\sigma_{1}(N)$$ I was able to show (in 2008) that $$\sigma_{1}({q_i}^{\alpha_i}) \le \frac{2}{3}\frac{N}{{q_i}^{\alpha_i}}$$ for all $i = 1, 2, ..., r = \omega(N)$, where N is an OPN (i.e. Odd Perfect Number) and ${q_i}^{\alpha_i} || N$ for all i. You will be able to get an upper bound for the logarithmic sum given above, by first taking logarithms of both sides of the inequality, then summing over all i. Unfortunately, for the "numbers" N that I am considering, the current literature (on OPNs) do not point to an approach "strong enough" to prove nonexistence of such "numbers" N. (This is because the upper bound alluded to in the previous paragraph is still (of course) dependent on $r = \omega(N)$). (And that is the reason why --) I'd be particularly interested in an analytic-number-theoretic approach. =) (Thanks to Gerry Myerson for encouraging this "clarification".)

Re: Mordell's equation $y^2 = x^3 + k$ and perfect numbers

I have already tried a somewhat exhaustive search of the literature, but couldn't find anything close to the problem that I am working on. My question is: When does Mordell's equation $$Y^2 = X^3 + K$$ have only finitely many solutions over the field of rational numbers, if we allow K itself to be a rational number? I've seen a "criterion" (i.e. a set of sufficient conditions) related to the class number of the (real/imaginary) quadratic field $\mathbb{Q}(\sqrt{K})$, but it is limited only to K being either 1 or 2 modulo 4. (The actual "criterion" (as stated in the Japanese[?] paper that I allude to) is: Mordell's equation $Y^2 = X^3 + K$ has finitely many solutions in $\mathbb{Q}$ if (1) $-K$ is not of the form $3t^2 + 1$ or $3t^2 - 1$; and (2) $K \equiv 1 \pmod 4$ or $K \equiv 2 \pmod 4$; and (3) 3 does not divide the class number of the (real/imaginary) quadratic field $Q(\sqrt{K})$.) Edit: Please refer to this hyperlink for more information as to the context of the previous "criterion". These have since been refuted by Kevin Buzzard (@Kevin - thank YOU!). Thanks to Kevin for pointing out some of the subtle errors in my original post, particularly in the third condition. I was considering the case $K > 0$ (i.e. for real quadratic fields). Now for the context: Let $$Y = W + Z$$ and $$X = WZ$$ where W and Z are defined as: $$W = I(p^k) = \frac{\sigma_{1}(p^k)}{p^k}$$ $$Z = I(m^2) = \frac{\sigma_{1}(m^2)}{m^2}$$ Let $$N = {p^k}{m^2}$$ be a perfect number. (At this point, we don't have to distinguish between even or odd N because the Euclid-Euler model for perfect numbers fits both cases. That is, the Eulerian form for an odd perfect number and the Euclidean form for an even perfect number have very similar multiplicative forms.) We "know" that the exponent k allows us to distinguish between even and odd N in the sense that: (1) If k = 1, then N is even. (2) If k > 1, then N is odd. hyperlink Perhaps the important feature that should be used to distinguish between even perfect numbers $M=2^{q-1}(2^q - 1)$ and odd perfect numbers $N=p^k m^2$ (where $2^q - 1$ and p are the Mersenne and special primes, respectively) is the index of a perfect number: (1) $\gcd(2^{q-1},\sigma(2^{q-1}))=1$ (2) $\gcd(m^2,\sigma(m^2))>1$ There is a known formula for computing $\gcd(m^2,\sigma(m^2))$. For example, if $k=1$, then it is equal to $2m^2 - \sigma(m^2)$. Thus, a (possibly) feasible and modern approach to the OPN problem (i.e. determining nonexistence or otherwise) will be to try establishing a finiteness result first (for particular values of K). In other words, checking for finiteness of OPNs amounts to checking for finiteness of solutions for Mordell's equation $$Y^2 = X^3 + K$$ for particular values of K. And you will only have to check for values of K in the range $[50, 399]$ (for a total of 350 elliptic curves), per the previous answer to this MathOverflow question. K falls in that range because the sum $$Y = W + Z$$ is known to lie in the open interval $(57/20, 3)$. Of course, the "juicy" implication is that: If you will be able to find a condition (e.g. equation, inequality, etc.) relating k to K and you are also able to further show that the number of solutions to the corresponding Mordell equation $Y^2 = X^3 + K$ is finite for all such K, then it would follow that there are only finitely many perfect numbers (odd and even). Disclaimer: This is a "naive" approach based on my current understanding of elliptic curve theory. I am well-aware, of course, that the rationals are dense over the real numbers. (Edit: In addition, the abundancy indices and the abundancy outlaws are both dense over the rationals.) Which is why I was kind of surprised that there is no need to assume ("strict") rationality (i.e. $K \in \mathbb{Q} \setminus \mathbb{Z}$) for K when checking for finiteness of solutions to Mordell's equation.

Conjecture about Euler quotients related to non-Wieferich numbers $W(n)=\frac{2^n+1}{3}$

For odd natural n define the Euler quotient: $$ a(n)=\frac{(2^{\phi(n)}-1) \bmod n^2}{n}=\frac{2^{\phi(n)}-1}{n} \bmod n$$ $a(n)=0$ is n being Wieferich number (not necessarily prime). For odd n, define $W(n)=\frac{2^n+1}{3}$. If $W(n)$ is prime, n is Wagstaff prime. Conjecture 1 $a(W(n)) \bmod 2=1$ for all odd $n>1$. Conjecture 2 $a(W(n))$ is nonzero all odd $n>1$. The Conjecture 1 will imply all $a(W(n))$ are non-zero and thus $W(n)$ non-Wieferich numbers. If n is prime all prime factors of $W(n)$ are congruent to 1 modulo n, and we will get infinite sequence of non-Wieferich numbers with unbounded smallest prime factor. Experimentally the conjecture holds for n up to 219 and factorization for computing the Euler totient is expensive. Computing the parity of other sequences gives random parity. Added per request for the code in comments. Here is sagemath code which you can run in a browser def W(n): return (2**n+1)//3 def V(n): return 2**n+1 def a(n,B=2): return lift((Integers(n**2)(B))**(euler_phi(n))-1)/n LAST=50 #limit for n for n in range(3,LAST,2): v1=n*(-V(n) + a(V(n))) + euler_phi(V(n)) v2=n*(-W(n) + a(W(n))) + 3*euler_phi(W(n)) print(n,v1==0,v2==0) #,a(V(n))/a(W(n))) """ pari/gp code ? a(N)=lift(Mod(2,N^2)^eulerphi(N) -1)/N %6 = (N)->lift(Mod(2,N^2)^eulerphi(N)-1)/N ? a(2^101+1) %7 = 25185665390673072597393245202 53 ? What is the status of this conjecture on symplectic forms "standard-at-infinity" on $\mathbb{R}^{2n}$?

In McDuff and Salamon's Introduction to Symplectic Topology, the following open problem is mentioned. Problem 50 (Standard-at-infinity) Let $n \ge 3$ and let ω be a symplectic form on $\mathbb{R}^{2n}$ that agrees with ω_0 on the complement of a compact set. Is $(\mathbb{R}^{2n}, \omega)$ symplectomorphic to $(\mathbb{R}^{2n}, \omega_0)$? In case it isn't clear, ω_0 is the standard symplectic form. The authors go on to mention some related results: The same question in dimension four has a positive answer by a celebrated theorem of Gromov [287]. A theorem of Floer-Eliashberg-McDuff [451] asserts that if (M, ω) is a symplectic manifold with $\pi_2(M) = 0$ that is symplectomorphic to $(\mathbb{R}^{2n}, \omega_0)$ outside of a compact set, then M is necessarily diffeomorphic to $\mathbb{R}^{2n}$. Mark McLean and others constructed many examples of symplectic structures on $\mathbb{R}^{2n}$ that are convex at infinity, but are not symplectomorphic to $(\mathbb{R}^{2n}, \omega_0)$ (see McLean [474, 475], Abouzaid-Seidel [6], and Seidel [576]). Since another open problem concerning the symplectic topology of Euclidean space was recently resolved, I became curious if any progress has been made on the problem stated above. I suppose this will likely be work performed since 2017, since that is when the most recent edition of McDuff-Salamon was published. I am particularly interested in the special case of $\mathbb{R}^6$. My questions are: What progress (if any) has been made beyond what is mentioned above? Is this problem known to be "very hard" by experts in the field? Does anyone have intuition on whether this is anything close to approachable by an average graduate student? Maximum number of connected components of surfaces in three dimensions, what is known?

Part of Hilbert's 16th problem is: It seems to me that a thorough investigation of the relative positions of the upper bound for separate branches is of great interest, and similarly the corresponding investigation of the number, shape and position of the sheets of an algebraic surface in space (...) The solution for a quartic surface is contained in Kharlamov: The topological type of nonsingular surfaces in RP3 of degree four. What is the status of this problem? In particular, is there a conjectural upper bound for the maximum number of connected components of a smooth degree d surface in $\mathbb{RP}^3$?

Conjecture on a cyclic quadrilateral associated with central line of triangle

Using computer I found a conjecture as follows (click to check by geogebra): Conjecture: Let A, B, C, D lie on a circle such that A, B, C, D are not formed an Isosceles trapezoid. Let AB meets CD at F and AD meets BC at E. Define $\ell(n, m, \triangle T)$ is a line through triangle center $X(n)$, $X(m)$ of triangle $\triangle T$, then $\ell(n, m, \triangle ABE)$, $\ell(n, m, \triangle CDE)$, $\ell(n, m, \triangle ADF)$, $\ell(n, m, \triangle BCF)$ form a cyclic quadrilateral for every positive integers n, m ($n \neq m$). Where $X(n)$ refer to Kimberling triangle center. Question: I am looking for a proof the conjecture above.

Conjecture closed form of summation over an integer lattice

Conjecture: $$\forall \Lambda,\ \exists P(x)\in \mathbb{Z}[x],\ S(\Lambda):=\sum_{k\in\Lambda}\prod_{j=1}^{n}\frac{1}{1+k_{j}^2}=\frac{\pi^{n}}{\sinh^{n}(\pi)\operatorname{d}(\Lambda)}P\left(\cosh\left(\frac{\pi}{\operatorname{d}(\Lambda)}\right)\right)$$ where $\Lambda=\bigl\{\sum_{j=1}^{n}a_j v_j|\ a_j \in \mathbb{Z}\bigl\}$, $V=\{v_1,\ldots,v_n\}$, $\operatorname{d(\Lambda)}=|\det(V)|\ $, V is an integer matrix. The conjecture is known to be true for $n=1$ or $\operatorname{d}(\Lambda)=1$, I also checked some few cases when $n=2$: $$\operatorname{d(\Lambda)}=2\implies P(x)\in \{4x^4-4x^2+2,\ 4x^4-2x^2\} \tag{1}$$ This corresponds to 2 lattice structures with $\operatorname{d(\Lambda)}=2$ in dimension 2. And for $V=\{(4,1)^T,(1,1)^T\}\implies P(x)=16x^6-24x^4+11x^2$; $V=\{(3,1)^T,(2,2)^T\}\implies P(x)=64x^8-128x^6+88x^4-24x^2+4$ As I mentioned in this previous question, I don't have a good way to compute this sum, all calculations and simplifications was done by calculator and each result took me quite a lot of time. Unfortunately, I cannot compute the sum when $n\geq 3$ because it is too much for my calculator to handle. However, partial calculation ($n=3$) suggested that closed form is achievable. Update Slightly deviated from

the main goal, I found out that $S(\Lambda)$ has a nice integral representation: $$\sum_{k\in \Lambda}\int_{\mathbb{R}^n}d^{n}x\exp{(-\|x\|_{1}+i\langle k,x \rangle)}=2^{n}S(\Lambda)$$ After some investigation, I think that $\sum_{k\in \Lambda} e^{i\langle k,x \rangle}$ is a distribution similar to Dirac comb, I couldn't find its formula though. If the formula of distribution is known, the integral can be turned into something like a geometric sum. I also noticed if that is the case, $\operatorname{d}(\Lambda)$ should be the "angular frequency". () (Edited) My question is: How do we find $$\sum_{k\in \Lambda} e^{i\langle k,x \rangle}$$ Does this give an answer to the conjecture?

Is it possible to discover a "Universal formula" that generates and generalizes all odd Collatz numbers?

I am just an ordinary student, and I have never had the chance to ask this question to mathematicians. Perhaps this is the first opportunity I have to ask it here. When we refer to "Collatz numbers", we mean all natural numbers that eventually reach 1 under the Collatz process. By odd-step Collatz numbers, we consider only the odd numbers that appear at each step of the sequence, skipping all even numbers. For example, for $n=4$, one possible sequence of odd-step Collatz numbers is: $$11 \rightarrow 17 \rightarrow 13 \rightarrow 5 \rightarrow 1 $$ Similarly, for $n = 6$, another example sequence could be: $$ 19 \rightarrow 29 \rightarrow 11 \rightarrow 17 \rightarrow 13 \rightarrow 5 \rightarrow 1 $$ Now, my question is: Is it possible to find a "Universal formula" (or something "magic formula") that generates all sequences of odd numbers with exactly n odd-steps in the Collatz process? For instance, consider a function like $f(n) = 2^n$. While this generates a sequence, it does not satisfy the criterion of producing a complete sequence of odd-step Collatz numbers, as it results in only one odd step. I use $f(n) = 2^n$ merely as an example to illustrate the kind of formula I am seeking. To summarize, for a given n, is there a general formula - similar to $f(n) = 2^n$ - that universally produces all sequences of n-step odd Collatz numbers? Has such a formula been discovered or studied by mathematicians? Thank you so much . I see that I needed to phrase the question more clearly. Let me rewrite what I mean by "Universal Formula". For example, when $n = 1$ is a finite number, we have a formula like $\dfrac {4^n-1}{3}$. We can go backwards and construct such a formulas for $n = 2$. But, it would be a great experience for me to learn whether a "formula" that directly depends on n exists or - if it is already known - to understand it .

The behaviour of $\mathsf{HOD}^{L[x]}$ on a cone

In "Introduction to Q-Theory" by Kechris-Martin-Solovay in the proceedings of the Cabal Seminar 1979 - 1981, back when it was believed axioms up to I_3 could be compatible with Δ^1_2-nondeterminacy, the following ultraproduct is introduced: $$\prod_{d \in \mathcal{D}} \mathsf{HOD}^{L[d]} / \mu$$ where μ is the Martin (cone) measure on Turing degrees $\mathcal{D}$, which is an ultrafilter assuming AD. Since the Martin measure is ω_1-complete, this ultraproduct is well-founded and its behaviour can be analyzed by analyzing the behaviour of $\mathsf{HOD}^{L[x]}$ for a cone of reals x (as if $x \in d \in \mathcal{D}$ then $L[x] = L[d]$). They write "this ultraproduct is understood as taken within $L(\mathbb{R})$", although I'm not sure how you would prove that every $f \in \prod_{d \in \mathcal{D}} \mathsf{HOD}^{L[d]}$ agrees with such an $f \in L(\mathbb{R})$ on a cone (maybe they just mean that you should compute it in $L(\mathbb{R})$ when you don't want to assume AD in V). Regardless, back then, it was expected that this would be "$\mathcal{M}^\infty$", an ultimate generalization of Mitchell's $L[\mathcal{U}]$ models that contains all Δ^1_3 reals. Indeed, they were partially right! In FSIT, the theory of inner models with a few Woodin cardinals was introduced, and M_1, the smallest inner model with a Woodin cardinal, was isolated as being a "canonical" Σ^1_3-correct model (a higher analogue of the Σ^1_2-correctness for $M_0 = L$ proven by Shoenfield absoluteness). In that paper, they prove $\mathcal{M}^\infty \cap \omega^\omega = M_1 \cap \omega^\omega = Q_3$ (the set of reals Δ^1_3 in a countable ordinal) and, if $\pi: \prod_{d \in \mathcal{D}} \mathsf{HOD}^{L[d]} / \mu \to \mathcal{M}^\infty$ is the Mostowski collapsing map, that $\pi(\langle \omega_1^{L[d]}: d \in \mathcal{D} \rangle)$ is measurable in $\mathcal{M}^\infty$. However, this 2018 answer by Goldberg indicates that the behaviour of $\mathsf{HOD}^{L[x]}$ is still mostly unknown. I am asking: Can $M_1^{L(\mathbb{R})} = (\mathcal{M}^\infty)^{L(\mathbb{R})}$, assuming $\mathrm{AD}^{L(\mathbb{R})}$? Has anything changed in the last 7 years? Apparently, $\mathsf{HOD}^{L[x][G]}$, for G an $L[x]$-generic for $\mathrm{Coll}(\omega, < \kappa)$, where κ is $L[x]$'s least inaccessible cardinal, was analyzed by Woodin, and I recall this 2020 paper by Müller-Sargsyan generalizing this to $\mathsf{HOD}^{M_n(x)[G]}$, but I still cannot find anything regarding $\mathsf{HOD}^{L[x]}$. Are there any papers describing the guess, mentioned in the above MO answer, that $\omega_2^{L[x]}$ is Woodin in $\mathsf{HOD}^{L[x]}$ on a cone (and hence $\pi(\langle \omega_2^{L[d]}: d \in \mathcal{D} \rangle)$ is Woodin in $\mathcal{M}^\infty$) due to iterated ultrapowers, or the result of Woodin, mentioned in "Introduction to Q-Theory" that there is a single, Sacks-like real s over $L(\mathbb{R})$ with $(\mathcal{M}^\infty)^{L(\mathbb{R})} = \mathsf{HOD}^{L[s]}$? Are these all in handwritten notes and personal communications, or have some facts been published since 1981?

Conjecture on the preservation of unfragmented sets under element addition

A set A_k contains k elements $a_i, i=1..k$. The a_i are incomparable (For example, functions, matrices, etc. they cannot be connected using > or <), but an operation $\otimes$ can be defined such that $a_i \otimes a_j$ holds for any a_i and a_j and satisfies the commutative law, and $a_i \otimes a_j$ are comparable. Therefore, from $a_i, i=1..k$, we can obtain $k(k-1)/2$ elements $b_{ij} \equiv b_{ji} \equiv a_i \otimes a_j \equiv a_j \otimes a_i$. These b_{ij} form a new set B_k. By sorting all elements in B_k from smallest to largest, we obtain the indices of the smallest $k-1$ elements, which total $2k-2$ numbers. Among these, the mode is s. If the count of s is $k-1$, then remove a_s from set A_k to obtain a new set A_{k-1} and repeat the above steps; if the count of s is less than $k-1$, then terminate. If the above operation removes all elements from A_k to obtain A_0, then A_k is called "fragmented"; otherwise, it is "unfragmented". Conjecture: For an unfragmented set A_k, after adding any element that satisfies the definition of A_k to A_k, A_k remains unfragmented. Please prove or disprove this conjecture.

Is the Invariant Subspace Problem interesting?

There's an amusing comment in Peter Lax's Functional Analysis book. After a brief description of the Invariant Subspace Problem, he says (paraphrasing) "...this question is still open. It is also an open question whether or not this question is interesting." To avoid lengthy discussions involving subjective views about what makes math interesting, I'd simply like to know if there are examples of math papers out there that begin with something like, "Suppose the invariant subspace problem has a positive answer..." Of course, papers that are about the ISP itself don't count!

Why is Erdős' conjecture on arithmetic progressions not discussed much, and is there an active pathway to its resolution?

Erdős' conjecture on arithmetic progressions (also known as the Erdős-Turán conjecture) is a major open problem in arithmetic combinatorics. It asserts that if the sum of the reciprocals of the members of a set A of positive integers diverges, then A contains arbitrarily long arithmetic progressions. Despite its fundamental nature and other well known theorems being a special case of it, the conjecture does not seem to be widely discussed in literature as much as it should. While I know some weaker results have been proven,the full conjecture remains open. My questions are: Are researchers actively working towards its resolution, and is there a specific pathway being pursued? What are the key difficulties that prevent a proof using current methods? Is there any expectation that this problem might be resolved in the near future, or is the problem considered beyond the reach of existing techniques? Any insights on the obstacles, possible strategies, and the current research landscape regarding this conjecture would be greatly appreciated

Perfect Numbers - On Mersenne and Euler Primes

Hi, I apologize if there is already an (obvious) answer to my question, but please bear with me for the moment as I find it hard to see a good way to answer this question: In the same way that the Mersenne primes uniquely determine the even perfect numbers (i.e. in the "bijective" sense), do the Euler primes likewise uniquely determine the odd perfect numbers? That is, while an Euler prime obviously maps to a single odd perfect number, it is not obvious to me that an odd perfect number could only map to a single Euler prime. This is because: (1) In the most general case, it is not known whether squares are friendly or solitary. (2) It is not even known if the smallest possible Euler prime 5 does divide an odd perfect number. (3) It is conceivable that two distinct numbers P and Q which satisfy a particular number-theoretic equation do not necessarily have to satisfy $\gcd(P, Q) = 1$. I hope you guys can help me out on this one. Establishing this very last gap will provide a proof for the implication: Assuming Sorli's Conjecture for OPNs is true, then there are no OPNs.

Reference request: Open problems about finite free products of finite groups

I'm working with finite free products of finite groups, i.e. a group G given by $$G = F_1 \ast \ldots \ast F_n$$ where each F_i is finite. Do you know of any open problems as well as references about them about these kinds of groups? In particular, I'm interested in finitely generated subgroups of such groups and related conjectures.

Furstenberg's topological proof method (of prime infinitude) might be more powerful than initially thought. $\sigma_0(\frac{p_n - 1}{4})$ odd i.o.?

Let $\sigma_0(n)$ be from number theory, i.e. the total number of divisors of an integer n. Let p_n denote the nth prime number. Let $S =$ the set of prime numbers $p \in 4\Bbb{Z} + 1$ such that $\sigma_0(\frac{p - 1}{4})$ is odd. Now generate the multiplicative submonoid M of $(\Bbb{Z}, \times)$ with $M = \langle 1,S \rangle$. Take as open topological basis the "Furstenberg-like balls" of the form $M\cap (a\Bbb{Z} + r)$, where $p \in S, a \in M$, and $r = 0..a-1$. And more importantly, where $M \cap (a\Bbb{Z} + r)$ is infinite. By convention $0 \notin \Bbb{N}$. Clearly $(M \cap a\Bbb{Z} + r) \cap (M\cap b\Bbb{Z} + s) = M\cap \operatorname{lcm}(a,b)\Bbb{Z} + t$, or the intersection is empty; where t is any element of the intersection. Satisfying the definition of topological basis.

Clearly, we retain the property that any open set is either empty or infinite, which will become important later. And so no complement of a non-empty finite set can be closed. The open ball $a\Bbb{Z} + r \cap M$ is also closed, it's complement clearly being equal to the union of all open balls over the residues of $s \neq r$ modulo a. Just as in Furstenberg's prime infinitude proof. Now if S were finite, then: $$ M\setminus \{1\} = \bigcup_{p \in S} M\cap p\Bbb{Z} $$ Which would lead to a contradiction, because the set of the right is closed and the set on the left is a complement of a finite non-empty set. As long as the equation is true. Clearly the left hand contains the right hand side. Now let $z \in$ the left hand side. Then $z =\prod_{i = 1}^m q_i^{n_i}$ such that $q_i \in S$. Then clearly $z \in q_i\Bbb{Z}$ for each $i=1..m$, hence $z \in M\cap q_i\Bbb{Z}$ and so is clearly in their union which is a subset of the right hand side. And we're done. Therefore, what I think I've proven is that: $$ \sigma_0(\frac{p_n - 1}{4}) \text{ is odd i.o.} $$ Question. Since this proof is elementary like Furstenberg's topological proof of the infinitude of primes, and it follows it pretty analogously, and there exists three-sentence proofs of the infinitude of primes; can you think of a very simple proof of the fact that $\sigma_0(\frac{p_n - 1}{4})$ is odd infinitely often? Note. I think the above proof might fail only at $M\cap a\Bbb{Z} + r$ always being infinite. So please don't take it as a real proof (yet).

The strong Mersenne conjecture

The strong twin conjecture: For every number $a≥0$, there exist two prime numbers p and $p+2$ such that $$a+4<p<2^{a+4}$$ and it was believed that this conjecture implies the twin conjecture. Then my question: Does there exist a similar stronger form of Mersenne conjecture formulated by using a double inequality. More generally, I am asking about the methods used to get a formulation like the one given in this question.

Can a uniformly-bounded Klein-Gordon wave sweep its nodal set across a rigid obstacle?

Consider Minkowski space $\mathbb R^{3+1}$ and the massive Klein-Gordon equation $$ \square\varphi + m^{2}\varphi = 0 . $$ Let $\Omega\subset\mathbb R^{3}$ be a fixed smooth bounded “obstacle’’ with boundary Σ. Does there exist a one-parameter family of smooth real solutions $\{\varphi_\varepsilon\}_{\varepsilon>0}$ such that: for every compact $K\subset\mathbb R^{3+1}$ the stress-energy tensor $T_{\mu\nu}[\varphi_\varepsilon]$ is bounded independently of ε. The canonical stress-energy tensor for a real massive Klein-Gordon field φ on Minkowski space $(\mathbb R^{3+1},\eta)$, with the mostly-plus signature $\eta = \operatorname{diag}(-1,+1,+1,+1)$, is given by: $$ T_{\mu\nu}[\varphi] = \partial_\mu\varphi\,\partial_\nu\varphi - \tfrac12\,\eta_{\mu\nu} \bigl(\partial^\alpha\varphi\,\partial_\alpha\varphi + m^{2}\varphi^{2}\bigr), \qquad \mu,\nu=0,1,2,3. $$ for each time t the nodal set $N_\varepsilon(t)=\{x:\varphi_\varepsilon(t,x)=0\}$ is a smooth surface; as $\varepsilon\to0$, the family $\{N_\varepsilon(t)\}$ converges (in the Hausdorff sense) to a prescribed smooth isotopy of embedded surfaces Σ_t that starts wholly outside Ω and ends wholly inside, so that the zero level set “passes through’’ the rigid boundary Σ. Informally, can one “vibrate’’ a Klein-Gordon field whose instantaneous nodal surface slides through an obstacle without the field’s energy blowing up? Standard geometric-optics constructions $$ \varphi_\varepsilon=\mathrm{Re}(a\,e^{iS/\varepsilon}) $$ appear to lose the required uniform bounds, while unique-continuation phenomena suggest obstructions when the evolving surface becomes characteristic. Note: The motivation for this problem came from the idea of “phasing” in fictional superhero stories. In particular, in the show The Flash, the main character has the ability to phase through solid objects by vibrating his molecules sufficiently fast.

Pillai's arithmetical function and primality

Pillai's arithmetical function is defined by $P(n)=\sum_{k=1}^n\gcd(k,n)$. Is it true that $1+P(n)\equiv 0\pmod{n}$ iff n is prime? It was stated without proof in 2014 on the OEIS A018804 and has since been reverted as a conjecture. A question posted last week on MSE didn't get a full proof: the case of squarefree composites with more than 3 factors is completely open. Do you have a reference or a proof for that case?

Primality test using the Golden Ratio

Background and Motivation The golden ratio, $$ \phi = \frac{1 + \sqrt{5}}{2}, $$ is a well-known irrational constant that appears frequently in geometry, algebra, and in the Fibonacci and Lucas sequences. Though fundamentally irrational and geometric, it surprisingly shows up in discrete number theory as well. Primality testing, on the other hand, is a central topic in number theory with both theoretical and practical importance, especially in cryptography. Most known primality tests rely on modular arithmetic, integer sequences, or algebraic identities - but very few, if any, directly involve irrational constants like ϕ. While experimenting numerically with powers of ϕ, I noticed an unexpected and elegant pattern. The simplicity and strength of this condition - despite its seemingly irrational origin - suggest a potentially deep connection between the golden ratio and prime numbers, possibly via the Lucas or Fibonacci sequences. This motivates the following natural questions: Why does this work? Is there a theoretical explanation rooted in recurrence sequences or algebraic number theory? Could this inspire a new class of primality tests? I am sharing this in hopes of uncovering deeper insights or connections that could explain the phenomenon. The Golden Ratio Primality Test (GRPT) If any positive integer $n>5$ is not divisible by 2 or 5, and satisfies the condition: $$ \lfloor \phi^n \rfloor \mod n = 1, $$ then, $$ n \text{ is

prime}. $$ Here, $$ \phi=\frac{1+\sqrt{5}}{2}.$$ Empirical Evidence I have verified GRPT for the range $5<n\leq 1{,}000{,}000 $ using Wolfram GPT. No false positives or false negatives found. Let's see how this applies to the first few $n>5$ (excluding the multiples of 2 and 5): $$\begin{array}{|c|c|c|} \hline n & \lfloor \phi^n \rfloor & \lfloor \phi^n \rfloor \mod n & \\ \hline 7 & 29 & 1 & \text{Prime}\\ \hline 9 & 76 & 4\neq1 & \text{Not prime}\\ \hline 11 & 199 & 1 & \text{Prime}\\ \hline 13 & 521 & 1 & \text{Prime}\\ \hline 17 & 3571 & 1 & \text{Prime}\\ \hline 19 & 9349 & 1 & \text{Prime}\\ \hline 21 & 24476 & 11\neq1 & \text{Not prime}\\ \hline 23 & 64079 & 1 & \text{Prime}\\ \hline 27 & 439204 & 22\neq1 & \text{Not prime}\\ \hline 29 & 1149851 & 1 & \text{Prime}\\ \hline 31 & 3010349 & 1 & \text{Prime}\\ \hline 33 & 7881196 & 4\neq1 & \text{Not prime}\\ \hline 37 & 54018521 & 1 & \text{Prime}\\ \hline 39 & 141422324 & 17\neq1 & \text{Not prime}\\ \hline 41 & 370248451 & 1 & \text{Prime}\\ \hline 43 & 969323029 & 1 & \text{Prime}\\ \hline 47 & 6643838879 & 1 & \text{Prime}\\ \hline 49 & 17393796001 & 29\neq1 & \text{Not prime}\\ \hline 51 & 45537549124 & 4\neq1 & \text{Not prime}\\ \hline 53 & 119218851371 & 1 & \text{Prime}\\ \hline 57 & 817138163596 & 4\neq1 & \text{Not prime}\\ \hline 59 & 2139295485799 & 1 & \text{Prime}\\ \hline 61 & 5600748293801 & 1 & \text{Prime}\\ \hline 63 & 14662949395604 & 41\neq1 & \text{Not prime}\\ \hline 67 & 100501350283429 & 1 & \text{Prime}\\ \hline 69 & 263115950957276 & 50\neq1 & \text{Not prime}\\ \hline 71 & 688846502588399 & 1 & \text{Prime}\\ \hline 73 & 1803423556807921 & 1 & \text{Prime}\\ \hline 77 & 12360848946698171 & 73\neq1 & \text{Not prime}\\ \hline 79 & 32361122672259149 & 1 & \text{Prime}\\ \hline 81 & 84722519070079276 & 22\neq1 & \text{Not prime}\\ \hline 83 & 221806434537978679 & 1 & \text{Prime}\\ \hline 87 & 1520283919093591604 & 62\neq1 & \text{Not prime}\\ \hline 89 & 3980154972736918051 & 1 & \text{Prime}\\ \hline 91 & 10420180999117162549 & 3\neq1 & \text{Not prime}\\ \hline 93 & 27280388024614569596 & 35\neq1 & \text{Not prime}\\ \hline 97 & 186982561199565069121 & 1 & \text{Prime}\\ \hline 99 & 489526700523968661124 & 76\neq1 & \text{Not prime}\\ \hline 101 & 1281597540372340914251 & 1 & \text{Prime}\\ \hline \end{array}$$ Why does this work? Can this become a deterministic primality test? Any insights, references, counterexamples, or theoretical developments would be greatly appreciated.

The Invariant Subspace Problem: examples

Question. Is there a concrete example of a bounded linear operator on a Hilbert space for which it is not known if it has a non-trivial closed invariant subspace? [Added 24.01.2011: According to Bernard Beauzamy (Introduction to Operator Theory and Invariant Subspaces, Elsevier (1988), p. 345), the operator which is "closest" to a counter-example is the one built by the present author: it has one hypercyclic point x_0, and for every polynomial p with complex coefficients, $p(T)x_0$ is also hypercyclic. Therefore, the operator has a vector space of hypercyclic points (thus solving a question raised by P. Halmos), but it may still have points which are not cyclic at all, thus having Invariant Subspaces. Beauzamy refers to his manuscript "The orbits of a linear operator". I have not been able to find an electronic version of this manuscript (or paper) online. Does anyone know where one may find a description of the example? Is it presently known whether the operator in Beauzamy's example has an invariant subspace?]

Which pairs of mutually contradicting conjectures are there?

Years ago I had the pleasure of witnessing Simon Thomas giving a wonderful talk about Martin's conjecture, which I just now fondly remembered reading this question. Even though I am not well-versed in all (or even many) fields of mathematics I find it quite curious that it was the only time I ever heard about two contradictory "official" conjectures. In chit-chat I definitely heard colleagues expressing different sentiments about which way a certain problem might finally be resolved but my guess is that they usually would not have been eager to put it in writing, possibly not even be happy to "go on the record". Also, the problem in question may have been a quite specific one relevant only to a small number of people... So...my question is: What are other example pairs(triples?) of that kind you are aware of? They ideally should have appeared in writing but I guess that I would be satisfied with conjectures which are ascribed to people by a nontrivial part of the (respective) mathematical (sub)community.

How can referees verify computationally intensive results when HPC resources are required?

This question is somewhat related to my previous question and is also inspired from this other question concerning the credibility of extensive computations (although from a different perspective). In the course of preparing a paper, I verified a conjecture computationally for a large range of cases. For small cases, I was able to run the computations on my laptop, since they required little RAM. However, at some point this was no longer feasible. At my university we have access to a high-performance computing (HPC) cluster, which allowed me to perform the larger calculations. This raises a concern: when the paper is submitted, the referee may wish to check the correctness of these computations. But what if they do not have access to an HPC cluster? In that case, they can only verify a portion of the claims. Is it sufficient to provide the raw output together with the code on GitHub/Zenodo, or is this not considered credible? After all, the raw output will consist of a .txt file that could, in principle, be tampered with (although doing so would clearly be dishonest, against all academic standards, and would eventually be detected by the community). My concern is precisely how referees can reasonably test such results in order to avoid this potential issue.

Prepending strings to primes.

Hello, we all know that 31,331,3331,33331,333331,3333331,33333331 all are primes, and that 333333331 is not. Here we prepend the digit 3 to 31, to get a list of 7 primes.This gives me the following thought: Let $$D = \{\text{all possible nonnull finite digit strings}\},$$ $$D' = \{\text{all things in D that do not start with 0}\}.$$ Define a function $m: D' \times D \to N \cup {\infty}$ by: $$m(A,B)= \min \{ k\geq 1 \colon A^kB \text{ is composite} \} - 1,$$ i.e., the number of consecutive primes at the beginning of the list $AB, AAB, AAAB, \dots$. For example, $m(3,1)=7$. Which values does m take? Is it unbounded? Is it ever ∞? This question has been posted to math.stackexchange too, and I got one comment talking about that it might involve Tao-Ziegler extension to the Green-Tao theorem, and so I thought it might be more appropriate here. So please, excuse me if it's posted wrongly, or if one shouldn't post to both channels.

An inequality that implies Frankl's union-closed conjecture

Let $\mathcal{F}$ be an union-closed family of subsets of $[n]=\{1,2,...,n\}$, assume $\varnothing\in\mathcal{F}$. Let $l_i=|\{S|S\in\mathcal{F},i\notin S\}|,u_i=|\{S|S\in\mathcal{F},i\in S\}|$, then $l_i+u_i=|\mathcal{F}|,\forall i\in[n]$. For a set $S\subset[n]$ (not necessary in $\mathcal{F}$), let $P_S=\prod_{i\notin S}l_i\prod_{i\in S}u_i$, M_S is the maximum set in $\mathcal{F}$ such that $M_S\subset S$ (which always exists because $\mathcal{F}$ is union-closed and $\varnothing\in\mathcal{F}$). Is the following inequality true? $$\sum_{S\subset[n]}P_{S/M_S}\leq|\mathcal{F}|^n$$ We could reduce Frankl's union-closed conjecture to the case $l_i,u_i>0,\forall i\in[n]$, then if the conjecture is false ($l_i>u_i,\forall i\in[n]$), then $P_S>P_R,\forall S\nsubseteq R\subset[n]$, so $P_S<P_{S/M_S}=P_{\varnothing}$ for non-empty $S\in\mathcal{F}$. We then have: $$|\mathcal{F}|^n=\sum_{S\subset[n]}P_{S}<\sum_{S\subset[n]}P_{S/M_S}$$ contradicting the above inequality.

Polynomial identification of natural numbers

Let n be an integer parameter. Is there a polynomial $f(x,y,n)\in \mathbb{Z}[x,y,n]$ such that $$ n\in \mathbb{N} \Longleftrightarrow \exists x,y\in \mathbb{Z}, f(x,y,n)=0? $$ This is a generalized form of the infamous Poonen Christmas problem. Bjorn's question boils down to the special case when $f(x,y,n)$ is of the form $cn+g(x,y)$ for some nonzero integer c and some $g(x,y)\in \mathbb{Z}[x,y]$. A formula by Raphael Robinson in Arithmetical definitions in the ring of integers, modified slightly as by Zhi-Wei Sun in A new relation-combining theorem and its applications (and reiterated by Mihai Prunescu in this paper) gives the following near example: $$ n\in \mathbb{N} \Longleftrightarrow \exists x,y\in \mathbb{Z}, (x^2-(4n+2)y^2-1=0) \land (y\neq 0). $$ "Open Question A" in Prunescu's linked paper is exactly my question.

No real roots of $\frac{1}{2^{1+it}} + \frac{1}{3^{1+it}} + \frac{1}{5^{1+it}}$

Prove or disprove that $$\frac{1}{2^{1+it}} + \frac{1}{3^{1+it}} + \frac{1}{5^{1+it}} \neq 0$$ for any real number t. I find it surprising that so simple looking equations involving complex numbers might turn out to be quite challenging to solve. For more context, see here, so I hope this gives a good motivation to discuss the problem here.

Minimizing an expression with sum of digits

Conjecture. If $S_b(n)$ denotes the sum of digits of n with base b then $$10 \cdot S_5(n)+12 \cdot S_2(n)-5 \cdot S_3(n) \geq 0$$ and the equality holds if and only if $n = 19925000$. The expression we look to minimize in this case is $$P(n) = 10 \cdot S_5(n)+12 \cdot S_2(n)-5 \cdot S_3(n).$$ It seems the minimium value of this is 0 and the maximum tends to infinity. Intuitively, to minimize $P(n)$ we want to maximize $\{\log_3(n)\}$ while simultanously minimizing $\{\log_2(n)\}$ and $\{\log_5(n)\}$. Of course, we have coefficients so it is not just as simple as this. But even if you look at cases like $n = 3^m-1$ it still does not get below 0. In this case my question would be to minimize the expression $$Q(n) = 10 \cdot S_5(3^n-1)+12 \cdot S_2(3^n-1)-2n.$$ In general, is it known how to minimize the expression $$P(n) = \sum_{i = 1}^m a_i S_{b_i}(n)$$ for some $a_i \in \mathbb{Z}$ and $b_i \in \mathbb{N}$ such that $b_i > 1$? In other words, under which conditions does the minimum value exist?

A conjecture on prime distribution (PKD Conjecture)

I would like to propose the following conjecture The PKD Conjecture (PKD) Let p,d be positive integers with $\gcd(p,d)=1$. There exists a function $$ f:\mathbb{N}\to\mathbb{N}, \quad f(N)<N, $$ such that there always exists an integer k satisfying $$ 0 < k \le f(\max\{p,d\}), \quad q = pk + d \text{ is prime}. $$ Special cases Case d,p: This reduces to the existence of the smallest prime in the residue class $d \pmod p$. This is related to Linnik’s theorem on the least prime in an arithmetic progression. Case $p=1$: This is equivalent to Cramér’s prediction, i.e. that there is a prime in the interval $$ (d,\, d+f(d)). $$ Heuristic A reasonable growth for f is expected to be $$ f(N) \sim e (\log N)^2, $$ which is consistent with Cramér’s conjecture on prime gaps. Motivation This conjecture can be viewed as a “meta-conjecture” that generalizes both: the distribution of

primes in arithmetic progressions (Linnik-type problems), and the distribution of primes in short intervals (Cramér-type problems). It suggests a unified framework for understanding prime distribution both along progressions and within bounded gaps. Question Is this conjecture a consequence of Montgomery’s conjecture? When $$ f(N) \sim e (\log N)^2, $$ Any references or insights would be greatly appreciated.

Pencils with many completely decomposable fibers

Let $F= \frac{G}{H} : \mathbb P^n \to \mathbb P^1$ be a non-constant rational function (G and H homogenous polynomials of the same degree in $\mathbb C^{n+1})$. The fiber over $(\lambda:\mu) \in \mathbb P^1$ is completely decomposable if all the irreducible factors of the polynomial $\mu G - \lambda H$ are linear polynomials. In a joint work with Sergey Yuzvinsky, we proved that when $n=4$ either (a) F, after a linear change of coordinates, belongs to $\mathbb C(x_0,x_1,x_2,x_3)$; or (b) F has at most three completely decomposable fibers. We couldn't come up with an example not satisfying (a), but with three completely decomposable fibers. Is anyone aware of an example like that ? Almost one year later: Let me describe the known examples of rational functions on $\mathbb P^3$ with three completely decomposable fibers. For every natural number $d \ge 1$, consider the rational function $F_d : \mathbb P^3 \to \mathbb P^1$ defined as $$ F_d(x_0:x_1:x_2:x_3) = \frac{(x_0^d - x_1^d)(x_2^d - x_3^d)}{(x_0^d - x_2^d)(x_1^d - x_3^d)} . $$ Clearly the fibers over $(0:1)$ and $(1:0)$ are completely decomposable. The fiber over $(-1:1)$ is also completely decomposable since $$ F^{-1}(1:-1) = \lbrace (x_0^d - x_3^d)(x_1^d - x_2^d) = 0 \rbrace \, . $$ For $d=1$, F_d can be written in fewer variables, but for $d \ge 2$ this is not the case.

Real approximation for homogeneous spaces of linear algebraic groups

Let X be a smooth geometrically integral variety over $\mathbf{Q}$, having a $\mathbf{Q}$-point. We say that X has the real approximation property if $X(\mathbf{Q})$ is dense in $X(\mathbf{R})$. Let now X be a homogeneous space of a connected linear algebraic group G defined over $\mathbf{Q}$. Since X has a $\mathbf{Q}$-point, we may write $X=G/H$, where H is a $\mathbf{Q}$-subgroup of G, not necessarily connected. Question 1. Does real approximation hold for any homogeneous space $X=G/H$ of any connected linear algebraic $\mathbf{Q}$-group G, where H is not necessarily connected? Serre proved real approximation for algebraic tori over $\mathbf{Q}$ (i.e. when G is a torus and $H=1$). Sansuc proved real approximation for connected linear algebraic groups over $\mathbf{Q}$ (i.e. when G is any connected linear algebraic group over $\mathbf{Q}$ and $H=1$). One can prove real approximation for homogeneous spaces with connected stabilizer (i.e. when G is a connected linear algebraic group over $\mathbf{Q}$, and $H\subset G$ is any connected $\mathbf{Q}$-subgroup). In the general case (i.e. when H is non-connected) I expect the negative answer, but I cannot construct a counter-example. The question can be stated in terms of Galois cohomology. Assume for simplicity that $G=\mathrm{SL}_n$, then $H^1(\mathbf{Q},G)=1$ and $H^1(\mathbf{R},G)=1$. Any orbit of $G(\mathbf{R})$ in $X(\mathbf{R})$ is open. If such an orbit contains a $\mathbf{Q}$-point, then $\mathbf{Q}$-points contained in this orbit are dense in this orbit, because our $G=\mathrm{SL}_n$ has real approximation. We denote by $G(\mathbf{R})\backslash X(\mathbf{R})$ the set of orbits of $G(\mathbf{R})$ in $X(\mathbf{R})$. Now our question is, whether the canonical map $G(\mathbf{Q})\backslash X(\mathbf{Q})\to G(\mathbf{R})\backslash X(\mathbf{R})$ is surjective. There is a canonical bijection $$ G(\mathbf{Q})\backslash X(\mathbf{Q})=\mathrm{ker}[H^1(\mathbf{Q},H)\to H^1(\mathbf{Q},G)]=H^1(\mathbf{Q},H) $$ and similarly $G(\mathbf{R})\backslash X(\mathbf{R})=H^1(\mathbf{R},H)$, so in this case Question 1 can be stated as follows: Question 2. Is it true that for any linear algebraic group H, defined over $\mathbf{Q}$ (not necessarily connected or abelian) the localization map $\mathrm{loc}_\infty\colon H^1(\mathbf{Q},H)\to H^1(\mathbf{R},H)$ is surjective? If the group H is connected or abelian, then the localization map loc_∞ is surjective (Sansuc's proof in the case of finite abelian H uses the Chebotarev density theorem and the fact that a decomposition group of ∞ is isomorphic to $\mathbf{Z}/2\mathbf{Z}$, hence cyclic). In the general case I expect the negative answer, i.e. that there exists a finite non-abelian algebraic group H over $\mathbf{Q}$ for which the localization map loc_∞ is not surjective, but I cannot construct such a counter-example.

A 2-fully normal space which is not finitely-fully normal

An open cover $\mathcal{U}$ has a n-star open refinement $\mathcal{V}$ if its a refinement such that if $V_1\cap ...\cap V_n\neq\emptyset$ and $V_k\in\mathcal{V}$ then $\bigcup_k V_k\subseteq U$ for some $U\in\mathcal{U}$. It has a finite-star refinement if it has a refinement which is an n-star refinement for all $n\in\omega$ (at the same time). A space is called n-fully normal if every open cover has n-star open refinement. It's a theorem of Goldman that this is equivalent to 2-fully normal. (here of course $n\in \omega$) A space is called finitely-fully normal if every open cover has a finite-star refinement. M. J. Mansfield conjectures the following: Not every 2-fully normal space is finitely-fully normal. I did try to search for it, but what came up are conjectures relating to the almost 2-fully normal property (strongly collectionwise normal) instead. In Almost n-fully normal spaces by K. P. Hart, this is question 4.9a, so it wasn't known in 1982. I assume this has been answered by now. Where can I find out about this? What do I read?

unboundedness of number of integral points on elliptic curves?

If $E/\mathbf{Q}$ is an elliptic curve and we put it into minimal Weierstrass form, we can count how many integral points it has. A theorem of Siegel tells us that this number $n(E)$ is finite, and there are even effective versions of this result. If I'm not mistaken this number $n(E)$ is going to be a well-defined invariant of $E/\mathbf{Q}$ (because different minimal Weierstrass models will have the same number of integral points). Is it known, or conjectured, that $n(E)$ is unbounded as E ranges over all elliptic curves? Note: the question is trivial if one does not put E into some sort of minimal form first: e.g. take any elliptic curve of rank 1 and then keep rescaling X and Y to make more and more rational points integral.

Are there infinitely many k such that $6k-1, \; 6k+1, \;$ and $12k-1$ are all prime?

I have been looking into the intersection of Twin Primes and Sophie Germain primes. Specifically, I am interested in whether a prime p can be both the "lower" member of a twin prime pair and a Sophie Germain prime. If p is the upper member of a twin prime pair, $p = 6k+1$ (for $k≥1$). Then $2p+1 = 2(6k+1)+1 = 12k+3 = 3(4k+1)$. This is always a multiple of 3, so $2p+1$ is never prime for k≥1. If p is the lower member, $p=6k-1$. Then $2p+1=2(6k-1)+1=12k-1$ My question: Is it conjectured (or known) that there are infinitely many k such that $6k-1$, $6k+1$, and $12k-1$ are all prime?

Status of linearity of mapping class group

This is a followup to this question on the status of the linearity of the mapping class group, which doesn't appear to me to have been satisfyingly answered. It seems to be agreed that this paper by Bigelow and Budney (2001) establishes the linearity of the mapping class group of a surface Σ_g for $g=2.$ On the other hand, this paper by Nikolaev (2003) claims a positive resolution of the question for any g. But Benson Farb in chapter 2 of this book (2006) and also Ozsvath, Lipshitz, and Thurston in this paper (2010) claim the problem is open. Has a mistake been found in the proof by Nikolaev? Why does there not seem to be much confidence in it?

How far is Scholze's vision for shtuka over $\operatorname{Spec} (\mathbb{Z})$ from realization?

How speculative is Scholze's vision for shtuka over $\operatorname{Spec} (\mathbb{Z})$? Intuitively, it appears very speculative. Primarily because shtuka are very much function field objects and in order to have a "shtuka" over a number field one needs very strict analogues of (1) the Frobenius and (2) a field of constants both of which are not available for number fields. Very recently Scholze gave a seminar on a new object he calls Gestalten. From what I understand, one of the major motivations for this was to create a "place" or "setting" that can unify or simultaneously handle both non-archimedean and archimedean algebraic geometry. I am wondering: does this new setting get one closer to this dream or does it make headway on either of the two major obstacles? Moreover, I am confused as to how such an object (Gestalten) should succeed in unifying the non-archimedean and archimedean worlds in a non-trivial way. Any answers both more generally and more narrowly relating Gestalten would be wonderful.

A 2D lattice generalization related to prime gaps and Cramér's conjecture

Conjecture: Let x and y be integers such that $1 < x < y$ and $\gcd(x, y) = 1$. There always exists at least one prime p of the form: $$p = n \cdot x + m \cdot y$$ where $n, m \ge 1$ are integers satisfying $n \le \lceil \ln^2(y) \rceil$ and $m \le \lceil \ln^2(x) \rceil$. Restricted Conjecture (Weak Form): Let x and y be primes ($x < y$). There always exists at least one prime p of the form:$$p = n \cdot x + m \cdot y$$ Where $n, m \ge 1$ are integers satisfying $n \le \lceil \ln^2(y) \rceil$ and $m \le \lceil \ln^2(x) \rceil$. The logarithmic bounds are structurally inspired by Cramér's conjecture. However, by strictly enforcing $x > 1$ and incorporating the parameters (x, y) as independent weights, this formulation intentionally shifts the problem from a classical 1D prime gap search into a 2D discrete lattice equipped with strict coprimality sieves. I have computationally verified this existence for all primes $x \le 10^5$ and $y \le 10^8$ with absolutely no counter-examples found. Moreover, I stress-tested the conjecture against extreme "death cases" where x and y are highly composite primorials (e.g., setting x as the product of the first 200 primes, $x \approx 10^{512}$, and y as the product of the next 5 primes). Interestingly, the empirical data shows that despite the coprimality filters severely throttling the available grid points (the survival rate of (n, m) pairs drops to approximately 15%), a prime is almost always found immediately at $n=1$ and a very small m (utilizing less than 0.1% of the m-bound), suggesting that the conjecture holds with a comfortable safety margin. Questions: Q1. Is it possible to give heuristic support for this conjecture for all values of x and y? Q2. Are existing bounds on prime gaps or primes in arithmetic progressions capable of fully resolving this problem, or does it require new sieve methods?

A mysterious statement by Martin and Solovay

D. A. Martin and R. M. Solovay, "Internal Cohen extensions", Annals of Mathematical Logic - Volume 2, No. 2 (1970) pp. 143--178, (MR270904, Zbl 0222.02075) say on page 166: Solovay will show elsewhere that II implies that $\aleph_1$ is a $0, 1$-measurable cardinal, so that II contradicts the axiom of choice. Here II is Lusin's hypothesis from N. Lusin, "Sur les ensembles analytiques nuls", Fund. Math. 25 (1935) 109-131 (JFM 61.0222.03, Zbl 0012.34401) saying that: (II) every union of a collection of constituents of a coanalytic set is again a coanalytic set. The supposed result by Solovay sounds very unusual as compared to typical solutions of problems of classical descriptive set theory. Is there anything known about any further development?

On $a^3+b^3+c^3 = N$ and $a^5+b^5+c^5+d^5+e^5 = N$

(Update, July 21, 2026): For $N<100$ and using a higher search radius, Simon Goater found, 55 = 38800^5 - 37045^5 + 22356^5 - 29644^5 - 15378^5 59 = 32064^5 - 32521^5 + 25162^5 - 23778^5 + 1078^5 while Jeff Braun found (June 27, 2026), 49 = -22403^5 + 21596^5 + 15669^5 + 4698^5 - 4001^5 Guruprasad's earlier search radius of $|x|<20000$ found 6 (and more) like, 38 = 9265^5 - 9258^5 - 3035^5 - 98^5 - 46^5 reducing unknown $N\leq100\,$ to $\,29-6-3 = 20$. I. Problem We are looking for integer near-misses of the Fermat quintic threefold, $$a^5+b^5+c^5+d^5+e^5 = 0\qquad$$ $\hskip1.5in$ where the sum, instead of vanishing, is some small integer $N<300$, preferably $N<100$. This threefold is a Calabi-Yau manifold. Note: Jeff Braun (mentioned above) found the fourth primitive integer solution with $N=0$. See paper. II. Third Powers The equation $a^3+b^3+c^3 = N$ has often been discussed in MO. For a small sample, see this, this, this. In a 1955 paper, Miller and Woollett used the early computer EDSAC to search $x_1^3+x_2^3+x_3^3 = N$ for positive $N<100$ with $N \not\equiv \pm\,4\, \pmod9.\,$ If they had used a very modest range of $|x|<30$, they wouldn't have found 12 N. Arranged by form, \begin{array}{|c|c|} \hline \text{Form} & \text{Missing N (3rd powers)} \\ \hline N\equiv 2 \pmod{9} & 74 \\ \hline N\equiv 3 \pmod{9} & 30, 39, \color{blue}{48}, 75, 84\\ \hline N\equiv 6 \pmod{9} & 33, 42,\color{blue}{51}, \color{blue}{78}, 87\\ \hline N\equiv 7 \pmod{9} & 52 \\ \hline \end{array} with none missing for $N\equiv 0 \pmod{9}$ and $N\equiv \pm1 \pmod{9}$. Miller and Woollett mentioned some $N\equiv \pm3 \pmod{9}$ were "difficult". But they actually used a search radius 100x higher at $|x|<3000$, and found just three additional numbers (in blue above) with the largest terms for $N=51$, $$51 = -796^3 + 659^3 + 602^3$$ so $12-3=9$ missing N. The next value, $N = 87$ was found ten years later in 1964 by Gardiner and Lazarus. Over the years, the search radius increased from $10^4, 10^6, 10^8,\dots,10^{18}$ (though not exhaustive) to find all 9 culminating in Booker and Sutherland's 2019, $$-80538738812075974^3+80435758145817515^3+12602123297335631^3 = 42$$ III. Fifth Powers A similar phenomenon seems to be at work for $a^5+b^5+c^5+d^5+e^5 = N$ which does not bode well for finding "smallish" solutions. Initial searches for small positive $N<100$ were done by DanielV and Guruprasad. If terms are $|x|< 10^3$ or less, then one can easily find 70 N but wouldn't find 29 N. Arranged by form, these are, \begin{array}{|c|c|} \hline \text{Form} & \text{Missing N (5th powers)} \\ \hline N\equiv 0 \pmod{11} & \color{red}{55} \\ \hline N\equiv 1 \pmod{11} & \color{blue}{89}\\ \hline N\equiv 2 \pmod{11} & 90 \\ \hline N\equiv 3 \pmod{11} & \color{blue}{58}, \color{blue}{80}, \color{blue}{91}\\ \hline N\equiv 4 \pmod{11} & 15, 26, 37, 48, \color{red}{59}, 81\,\;\; \quad \\ \hline N\equiv 5 \pmod{11} & 16, 27, \color{blue}{38},\color{red}{49}, 60, 82, 93\; \\ \hline N\equiv 6 \pmod{11} & 39, 72\; \\ \hline N\equiv 7 \pmod{11} & 7, 40, 51, 73, 84 \\ \hline N\equiv 8 \pmod{11} & 41 \\ \hline N\equiv 9 \pmod{11} & 9,\color{blue}{42} \\ \hline N\equiv 10 \pmod{11} & none\\ \hline \end{array} Note: Adam Bailey pointed out that the difficult N would be the four forms $N\equiv \pm4 \pmod{11}$ and $N\equiv \pm5 \pmod{11}$ as seen in the table above. Guruprasad extended the search radius to $|x|<\color{blue}{10^4}$ and found six additional numbers (in blue), though only N = 38 has terms $|x|>5000$, $$38 = 9265^5 - 9258^5 - 3035^5 - 98^5 - 46^5$$ Jeff Braun and Simon Goater went higher and found N = 49, 55, 59 (in red). So $29-6-3=20$ are missing, namely, N = 7, 9, 15, 16, 26, 27, 37, 39, 40, 41, 48, 51, 60, 72, 73, 81, 82, 84, 90, 93 IV. Higher N For the higher range $N<300$, Simon Goater searched terms $|x_i|<4000$ and Guruprasad extended to terms $|x_i|<20000$, \begin{array}{|c|c|} \hline \text{Range}\; R_n & \text{# of missing}\, N & \text{# of missing}\, N & \text{# of missing}\, N\\ & \text{if}\, |x|<10^3 & \text{if}\, |x|<10^4 & \text{if}\, |x|<10^5 \\ \hline \quad 1\leq N \leq100 & 29 & 23 & 20\,?\\ \hline 101\leq N\leq200 & 39 & 30 & 27\,?\\ \hline 201\leq N\leq300 & 36 & 28 & 25\,?\\ \hline \end{array} Notice that, just like for 3rd powers, with increasing search radius $10^3\to10^4$, the number of missing N reduces. So what happens when $10^4\to10^5$? It seems they go down. The counts in the third search radius reduced when N = 49 was later found by Jeff Braun, N = 126, 169, 184, 289 by Eugene Go, and N = 55, 59, 228, 233 by Simon Goater. Updated missing N of range R_n are: R_1 = 7, 9, 15, 16, 26, 27, 37, 39, 40, 41, 48, 51, 60, 72, 73, 81, 82, 84, 90, 93 R_2 = 103, 104, 105, 106, 112, 114, 116, 117, 132, 134, 135, 136, 137, 138, 139, 149, 153, 158, 159, 161, 170, 171, 172, 183, 191, 194, 196 R_3 = 203, 205, 215, 222, 224, 226, 229, 235, 236, 238, 248, 249, 258, 264, 268, 269, 270, 279, 280, 281, 290, 291, 292, 293, 297 V. Question What is a good method to reach higher bounds and find more missing $N<300$? Is it Guruprasad's sieve-based, meet-in-the-middle algorithm, or Jeff Braun's method to find $x_1^5+x_2^5+x_3^5+x_4^5+x_5^5 = N$ for $N=0$ described in his paper, or can the methods for $x^3+y^3+z^3=N$ be modified for 5th powers? Note: By the Easier Waring's Problem, then $5\leq v(5)\leq 10$. There is no mod obstruction, so we assume $v(5)=5$.

Can an integer reciprocal series remain rational after a unit shift in the denominator?

Let a_n be an infinite sequence of positive integers (not necessarily distinct), and for this sequence, $$ \sum_{n=1}^{\infty}\frac{1}{a_n} $$ converges. Define $$ S(k)=\sum_{n=1}^{\infty}\frac{1}{a_n+k}, \qquad k\in\mathbb{Z}_{\ge0}. $$ My question is whether there exists any such sequence a_n for which both $$

S(0)\in\mathbb{Q} \quad\text{and}\quad S(1)\in\mathbb{Q}. $$ Equivalently, can one prove that this is impossible? The sequence is allowed to have repeated values; the only assumptions are that every a_n is a positive integer and the series converges. I know that if the a_n are allowed to be arbitrary positive real numbers, then such examples exist by construction, so does if negative integers are allowed using telescoping series, so the positive integrality of the sequence is the essential restriction here. If this is known, I'd appreciate either a reference or an explicit example. Otherwise, a proof that no such sequence exists would also answer the question.

Conjecture : $\forall n>3 , \text{gpf}(y_n)>\text{gpf}(y_1)$

Let $n \in \mathbb{Z}_{>1}$, we call $\text{gpf}(n)$ the greatest prime factor of n Take $d \in \mathbb{Z}_{>1}$ a squarefree integer, we call (x_n,y_n) the n-th pell solution of $x^2-dy^2=1$ Can you show that $\forall n>3 , \text{gpf}(y_n)>\text{gpf}(y_1)$? For instance, If $d=263$ we have $x_1=139128$ and $y_1=8579=23 \times \color{red}{373}$ $$y_2=2^4 \times 3 \times 11 \times 17 \times 23 \times 31 \times \color{red}{373}$$ $$y_3=5 \times 7 \times 19 \times 23 \times 29 \times 101 \times 127 \times 313 \times \color{red}{373}$$ $$y_4=2^5 \times 3 \times 11 \times 17 \times 23 \times 31 \times \color{red}{373} \times 184913 \times 209359 $$ However, the next values of y_n seem to be divisible by really huge primes ! e.g : $\text{gpf}(y_{17})=152978144089051842195133050091524167 41 \approx 1.53 \times 10^{37}$ and so can we find in general a lower bound like $\text{gpf}(y_n)>f(n,y_1)$ for $n\ge n_0$? I know only few results about the size of primes dividing y_n, like this one by D. H. Lehmer in Lemma 5 : if $n>3$, y_n is divisible by a prime $\ge 2n-1$ and so for $n>3$, we can say $\text{gpf}(y_n) \ge 2n-1$ However, this lower bound doesn't account for the size of primes dividing y_1 (in our case 23 and 373) so a lower bound like $\text{gpf}(y_{17})\ge 2\times 17-1=33$ is so useless :-(because $y_1 \mid y_n$, so $\forall n\ge 1$ we have $\text{gpf}(y_n)\ge \text{gpf}(y_1)=373$ already bigger than 33 So an elementary function f we can deduce for $n>3$ is $f(n,y_1)=\max(2n-1,\text{gpf}(y_1))$ and could one points me towards published results of the same nature ? Thanks for help :-)

Is Gardam's support-21 unit in $\mathbb{F}_2[P]$ (Promislow group) support-minimal?

Gardam [1] disproved the Kaplansky unit conjecture by exhibiting a nontrivial unit α of support size 21 in $\mathbb{F}_2[P]$, where $P = \langle a,b \mid b^{-1}a^2b = a^{-2},\ a^{-1}b^2a = b^{-2}\rangle$ is the Promislow group, and remarks that it is "plausible" that every nontrivial unit has support size at least 21. Craven-Pappas [2] had verified the unit conjecture in $K[P]$ for supports of dihedral length at most 3. Since then, computational searches for units and zero divisors of small support in a group-agnostic setting have been carried out by Garg-Mineyev [4], with a structural obstruction to that framework proved by Shin [5]; as far as I can tell, these do not directly address support minimality inside $\mathbb{F}_2[P]$ itself. Setup. Write elements of P as $x^i y^j z^k \sigma$ with $x=a^2$, $y=b^2$, $z=(ab)^2$, $\sigma \in \{1,a,b,ab\}$, and fix the asymmetric boxes B_1 (the 108 elements with $|i|,|j|,|k|\le 1$) and B_2 (the 500 elements with $|i|,|j|,|k|\le 2$); Gardam's unit and its inverse have supports inside B_1 and B_2. Over $\mathbb{F}_2$, the equation $\alpha\beta=1$ is a parity condition: every group element $w \ne 1$ must have an even number of factorizations $w = gh$ with $g \in \operatorname{supp}\alpha$, $h \in \operatorname{supp}\beta$, and $w=1$ an odd number. Existence of such supports inside the boxes is a finite decision problem, which we solve with SAT solvers, together with a bound on $|\operatorname{supp}\alpha|$ and, optionally, the support symmetry of [1, Lemma 1]. The setup is validated by reproducing $\alpha\alpha^{-1}=1$ for Gardam's unit in an independent implementation of P. Current computations (certificates and code: github.com/Divide-By-0/promislow-unit-minimality): A support-21 unit is re-found in $B_1 \times B_2$ and verified by exact multiplication in $\mathbb{F}_2[P]$. No unit pair exists with $\operatorname{supp}\alpha \subseteq B_1$, $\operatorname{supp}\beta \subseteq B_2$, $|\operatorname{supp}\alpha| \le 20$, and both supports symmetric in the sense of [1, Lemma 1] (solver-level, all $k \le 20$). For $|\operatorname{supp}\alpha| \le 16$ in the symmetric class (with no gauge normalization), the impossibility additionally carries machine-checkable proofs of unsatisfiability, validated with an independent proof checker. The computation aiming at the full range $|\operatorname{supp}\alpha| \le 20$ over $B_1 \times B_2$ with no symmetry assumption, with certificates throughout, is in progress. We regard the symmetric-class results as computational evidence and validation of the pipeline; even the completed unrestricted computation would be a finite-region statement, not the global theorem. Hence the actual questions: Question 1. Is a global lower bound on the support size of nontrivial units of $\mathbb{F}_2[P]$ (beyond the length-based results of [2]) known or announced? Is the global statement "every nontrivial unit has support size at least 21" believed to be within reach of current structural methods? Question 2. Are there structural arguments - via the dihedral-length analysis of [2], the structure theory of $(\mathbb{F}_2[P])^\times$ in [3], or otherwise - that would reduce every hypothetical unit of support size < 21 to finitely many configurations, e.g. by confining its support to an explicit finite region of P? That reduction is what would turn finite certified computations like the above into a proof of global minimality, and seems to be the conceptually valuable step. Question 3. Is anything known toward classifying the support-21 units up to multiplication by trivial units, inversion, and automorphisms of P? Independently found units (Gardam's, Murray's char-p variants, the char-0 units, and the SAT re-discoveries) land at support exactly 21, and a classification would explain the recurrence of 21 rather than merely confirm it numerically. Was a computational hardness argument ever used to solve a mathematical conjecture?

Let P be a property of positive integers. Suppose that $P(n)$ can be decided in finite time, but all known algorithms take a long time. Based on experiments done so far, it is conjectured that $P(n)$ holds for all n. Now someone proves, using computer science methods, that deciding $P(n)$ is NP-hard (or hard in some other complexity class). This immediately refutes the above conjecture, since if the conjecture were true, the decision problem would have been trivial. Has such a story ever happened?

Checking one group for torsion

Let's consider such a group $$ G = \langle a, b, c, d \mid r_1, r_2, r_3, r_4, r_5, r_6, r_7 \rangle, $$ where $$ \begin{aligned} r_1 &= dcb c^{-1}d^{-1}bab^{-1}a^{-2},\\ r_2 &= cdc^{-1}d^{-1}a^{-1}b^{-1}acdb^{-2},\\ r_3 &= babdb^{2}d^{-1}c^{-1}a^{-2}c^{-1}d^{-1},\\ r_4 &= dcdb^{-1}d^{-1}a^{-1}c^{-1}db^{2}d^{-1}c^{-1}a^{-1},\\ r_5 &= dcdacdb^{-2}d^{-1}a^{-1}b^{-1}d^{-1}c^{-1},\\ r_6 &= dcabd^{-1}b^{-2}d^{-1}acdb^{-2},\\ r_7 &= badcb^{-1}d^{-1}a^{-1}c^{-1}acdb^{-2}d^{-1}. \end{aligned} $$ I found this group in my records. It is noteworthy that its group ring $Z[G]$ contains non-trivial zero-divisors. I can't provide them yet, because I'm not near the notebook where it was written out. In the future, I will update the post and provide them. First, a divisor of zero was built, and then a group G on relations that allow $\alpha\beta = 0$ in $Z[G]$. The motivation for considering this group is connected with Kaplansky's hypothesis about zero-divisors in group rings: Let G be a torsion-free group and K be a field. Then $K[G]$ does not contain zero-divisors. I examined this group for torsion, but I could not find an obvious torsion. I know that it is incredibly difficult to check a group with a random representation for torsion. Therefore, my question is: are there any techniques applicable specifically to this group that could prove\refute the presence of torsion? Is it possible to provide any relatively easily calculated signs that can give some information about the torsion in it? Is it possible to get any indirect information about torsion in this group using a computer? Can any GAP\Sage functions help with this? So far, all the functions I used have not been able to complete their work and give the final answer. Still, it's quite possible that I didn't see an obvious torsion. A couple of facts about this group: It's perfect. That is, $G = [G, G]$. Some relations contain quite large common bites. For example, $acdb^{-2}$. UPD: There is a zero divisor in $Z[G]$: $$AB = (d^2 c a + d^2 c d + d c b a - d b a b - d c d b a - a^2 b^2) (d b^2 d + d^2 c a b + a c d^2 - d c d - b a d c - c a d b)$$ Let's rename the terms. $$AB = (w_1 + w_2 + w_3 - w_4 - w_5 - w_6)(w_7 + w_8 + w_9 - w_{10} - w_{11} - w_{12})$$ In G, it is satisfied: \begin{align} &1. \quad w_1 w_7 = w_4 w_8 \\ &2. \quad w_1 w_8 = w_4 w_9 \\ &3. \quad w_1 w_9 = w_4 w_7 \\ &4. \quad w_2 w_7 = w_5 w_8 \\ &5. \quad w_2 w_8 = w_5 w_9 \\ &6. \quad w_2 w_9 = w_5 w_7 \\ &7. \quad w_3 w_7 = w_6 w_8 \\ &8. \quad w_3 w_8 = w_6 w_9 \\ &9. \quad w_3 w_9 = w_6 w_7 \\ &10. \quad w_4 w_{10} = w_1 w_{11} \\ &11. \quad w_4 w_{11} = w_1 w_{12} \\ &12. \quad w_4 w_{12} = w_1 w_{10} \\ &13. \quad w_5 w_{10} = w_2 w_{11} \\ &14. \quad w_5 w_{11} = w_2 w_{12} \\ &15. \quad w_5 w_{12} = w_2 w_{10} \\ &16. \quad w_6 w_{10} = w_3 w_{11} \\ &17. \quad w_6 w_{11} = w_3 w_{1} \\ &18. \quad w_6 w_{1} = w_3 w_{10} \end{align} You can set up a group with these relations in Sage, and using the G.simplified() function, get exactly the same representation as in the post.

Are there infinitely many primes of the form $\hspace{1mm} {}^b a \pm {}^a b$, with integers $a,b\geq 2$?

Let ${}^b a$ denote the tetration of a to height b (e.g., ${}^3 3=3^{3^3}=3^{27}=7625597484987$). I am interested in primes of the forms ${}^b a+{}^a b$ and ${}^b a-{}^a b$, where $a,b \geq 2$ are integers (I came across this problem while I was computing the first terms of the more general sequences of primes of the form ${}^b a \pm {}^d c$, with $a,b,c,d\geq 2$, for submission to the OEIS). Now, the only two terms I found of the more restrictive forms ${}^b a \pm {}^a b$ are: ${}^3 2+{}^2 3=16+27=43$ and ${}^2 3-{}^3 2=27-16=11$ (trivially, to be an odd prime, a and b must have opposite parity). Question. Are there any other primes of the form ${}^b a + {}^a b \hspace{1mm}$ or $\hspace{1mm} {}^b a - {}^a b$? If yes, are there infinitely many primes of either form? Remark. At a naive heuristic level, it is not clear to me what to expect: it seems that there are no immediate obstructions to primality beyond parity, while the extremely rapid growth of tetration makes prime values increasingly unlikely. Even partial results for either the sum or the difference would be of interest.

Is Murasugi's conjecture still open?

Normalize the Alexander polynomial (in t) so that the positive and negative exponents are balanced. For example in the Conway normalization, make the substitution $z = t^{1/2} - t^{-1/2}$. The trefoil gives $t^{-1} - 1 + t$. Conjecture: Suppose that K is an alternating knot. Then the sequence of absolute values of the coefficients is unimodal. Specifically, if $\Delta_K(t) = \sum_i a_i t^i$, then $|a_0| \ge |a_1| \ge |a_2| \ge \cdots$. This is a conjecture due to Murasugi, I believe. Where is it written? Has this been proved or disproved?

A recursive overlap construction of finite Bernoulli-sum laws and an entropy-concavity conjecture

Let (a_{n}) be a strictly increasing sequence of integers with $a_{1}=2$. Define probability vectors $P_n\in\mathbb R^{a_n}$ by $ P_1=(p,1-p)$ and $$ P_{n+1} = p\,L(P_n)+(1-p)\,R(P_n), $$ where the “left’’ and “right’’ embedding operators $ L:\mathbb R^{a_n}\to\mathbb R^{a_{n+1}}, R:\mathbb R^{a_n}\to\mathbb R^{a_{n+1}} $ are given by $$ L(P_n)=(P_n,0,\ldots,0), \quad R(P_n)=(0,\ldots,0,P_n). $$ Is the entropy of P_{n} concave in p? This is easy to prove for the non overlapping case $a_{n}\ge 2^n$ and fairly easy to prove for $a_{n}=n+1$. I tried to prove it for $a_{n}=n^2+1$ and Fibonacci like sequences given by $a_{n+1}=a_{n}+a_{n-1}+1$, which are of special interest for me, but I did not succeed. I ask ChatGpt to give me a Mathematica Code to test the conjecture. For any sequence that I tested up to $n=30$ (and for some sequences up to n=100) it seems to be true. But honestly I do not understand the mechanism. I have now written an preprint https://arxiv.org/abs/2609.05546 on the problem.

Adaptive prime window conjecture, does a previous prime gap correlate with the following one?

I am looking for feedbacks on my conjecture which I worked on for almost a year now. I'll define the conjecture with the following definition: For every integer $x>2$, let p_x denote the largest prime strictly less than x, and let $d_x=x-p_x$ denote the distance from x to the preceding prime. Let q_x denote the smallest prime strictly greater than x, and define $g_x=q_x-x$ as the distance from x to the following prime. I conjecture: $${ g_x \leq \left\lceil 2e^{-\gamma} \left[\left(\ln\frac{x}{d_x}\right)^2+2 \right] \right\rceil }$$ where γ is the Euler--Mascheroni constant. Originally I was not using x but rather p, meaning I thought this was working only if the input was a prime number, however since the computation works with any integer I believe x represents even a stronger claim. Let's look at an example: $ x=23 $ $ p_x=19 $ $ q_x=29 $ $ d_x=23-19=4 $ $ g_x=29-23=6 $ $$\left\lceil 2e^{-\gamma} \left[\left(\ln\frac{23}{4}\right)^2+2 \right] \right\rceil =6$$ ${g_x\leq6}$$ Findings connected to this conjecture: A larger preceding gap makes the upper bound smaller It holds from 2 up to 10^8, and it has been tested with random samples (window sizes of 1.000.000) up to 10^{20} The Nicely gap (x = 1693182318746371) would have broken the conjecture without adapting it to the Cramér-Granville conjectural model. No other exception was found by removing the factor $2e^{-\gamma}$ It is on average tighter than Cramér's conjecture by 15%, scaling according to the size of d_x, reaching tightness discrepancies above 90% in some cases Pattern driven by negative lag-1 autocorrelation (r ≈ -0.03) On point 5, Gideon Afriyie (2026) independently computed lag-1 autocorrelation on 50 million primes and reported r ≈ -0.0276 in his published paper (https://www.sciencedirect.com/science/article/pii/S0167715226002622) While the formula holds for any X bigger than 2, the striking observation is that, in the vast majority of cases, the tightest value in the whole interval occurs at the prime at the left endpoint of the gap. On point 7: Defining "normalized tightness" a following: $$[R(x)= \frac{g_x}{2e^{-\gamma}\left[(\ln(x/d_x))^2+2\right]}]$$ From my current computation, the tightest value in the whole interval occuring at the prime at the left endpoint of the gap it is already clearly above 95% of the prime-gap intervals. I am in the process of rerunning the calculation carefully, because I suspect the actual figure is around 99%, but I don't want to claim the exact percentage until I have checked it again. There are interesting exceptions. For example, $$[31397<31411<31469]$$ where (31397) and (31469) are consecutive primes and (31411) is composite. At the prime (x=31397) $$[d_x=4,\qquad g_x=72]$$ giving $$[R(31397)\approx0.778]$$ But at the interior composite (x=31411), $$[d_x=14,\qquad g_x=58]$$ and $$[R(31411)\approx0.839]$$ So this is a genuine example where an interior composite point is tighter than the preceding prime, although this appears to be relatively uncommon. Any feedback would be appreciated. I don't have a formal math education and I am spending my spare time on this project. Therefore I will try my best to engage with whoever wants to spend his/her time in having a look at what I assembled.

Almost-primes produced by $n^2 + n + (d+1)/4$ for a positive proportion of fundamental discriminants?

I arrived at the question below through an extended exploration that began with the classical Euler polynomials $n^2 + n + p$ and the Rabinowitsch-Heegner connection, and gradually moved toward more approachable variants. I am not a number theorist; the formulation and the suggested attack emerged from a long dialogue with an AI system (Grok), which I used to survey the landscape, test successive weakenings, and identify plausible analytic obstacles. I am sharing both the problem and a brief account of the process in case either is useful. Motivation. It is classical that $n^2 + n + p$ takes prime values for all $n = 0, \dots, p-2$ if and only if $4p-1$ is a Heegner number. Only six such primes p exist. For a general prime p (or a general fundamental discriminant $d = 4p-1$) one still expects the polynomial to produce primes for many n, but even the existence of a single extra prime value for every large p appears open and is essentially a special case of Bunyakovsky-type problems. A natural weakening is to ask only for almost-primes, and only for a positive proportion of

discriminants. Open problem. Do there exist constants $\theta > 0$ and $\alpha > 0$ such that for a positive proportion of fundamental discriminants $d \le Y$ (as $Y\to\infty$), there is an integer n with $1\le n\le d^\theta$ for which $$n^2 + n + \frac{d+1}{4}$$ is either a $P_{r-\text{number}}$ for some fixed r, or at least has a prime factor larger than d^α ? Suggested approach and apparent obstacles. One can view the values as norms of elements $n + \frac{1+\sqrt{-d}}{2}$ in the quadratic order of discriminant -d Averaging over fundamental discriminants places the problem in a setting where tools from the theory of L-functions of quadratic characters and class-group characters are available. A plausible route is: establish a usable averaged level of distribution for the sequence (or for the principal binary quadratic form of discriminant -d) when summing over fundamental discriminants; apply a modern sieve (combinatorial or multidimensional) to detect almost-primes in the short range $n\le d^\theta$; control the fluctuation of the class number $h(-d)$ and possible exceptional zeros. The most serious gaps appear to be obtaining a sufficiently strong and uniform averaged level of distribution, and handling the variation of $h(-d)$ while retaining a positive-density set of good discriminants. Questions for the community. Is a result of this strength already known, or does it follow quickly from existing theorems on almost-primes represented by binary quadratic forms averaged over discriminants? Are there stronger partial results (for example, for a thinner set of discriminants, or with a larger number of prime factors) that are already in the literature? Does the suggested approach look viable with current technology, or are there fundamental obstructions I have missed? Are there natural further weakenings (or strengthenings) that would make the problem more attractive? I am aware that the problem is far from my own expertise. My hope is that the formulation is clear enough to be useful, and that the transparent account of how it was reached may illustrate one way AI tools can assist in exploring and refining questions in analytic number theory. Thank you for any comments or references.

Is every generalized variety finitely accessible?

Is every generalized variety (definition below) finitely accessible? If not, what is a counterexample? A finitely accessible category is a category with filtered colimits and an essentially small collection of finitely presentable objects that generate the category under filtered colimits; here an object is finitely presentable when its hom-functor preserves filtered colimits. Replacing "filtered colimits" with "sifted colimits", we obtain the notion of a generalized variety, studied by Adamek-Rosicky in On sifted colimits and generalized varieties (TAC): this is a category with sifted colimits and an essentially small collection of strongly finitely presentable objects that generate the category under sifted colimits; here an object is strongly finitely presentable when its hom-functor preserves sifted colimits. In the end of the mentioned paper, the authors remark that every generalized variety is $\aleph_1$-accessible, and they ask if every generalized variety is finitely accessible. This was an open problem when the paper was written. But this was 25 years ago, so maybe we have more insights now. Among the 52 generalized varieties currently recorded in CatDat, all are finitely accessible. But there are many finitely accessible categories that are no generalized varieties. Every cocomplete generalized variety is a variety (Theorem 3.10 in op. cit.) and therefore finitely accessible.

Has AI made any progress as a mathematical theory-builder, rather than just a problem-solver?

In his essay The Two Cultures of Mathematics, Timothy Gowers distinguishes between two broad mathematical cultures: problem-solvers and theory-builders. Recent advances in AI-assisted mathematics seem to demonstrate increasingly impressive problem-solving abilities, including progress on difficult open problems. However, I wonder whether comparable progress has been made on the other side of Gowers's distinction. By theory-building, I mean something more than proving new theorems or solving existing conjectures: for example, introducing genuinely useful mathematical concepts, definitions, structures, or frameworks that unify previously disconnected results, suggest new research directions, or fundamentally change how a mathematical subject is understood. Are there documented examples of AI systems making original contributions of this kind to mathematical research? I am particularly interested in cases where the AI contributed substantially to the conceptual framework itself, rather than merely helping prove results within a framework already developed by humans. I realize that the distinction is not sharp, and that the originality and mathematical significance of a new conceptual framework can be difficult to assess. I would welcome references to concrete examples, including unsuccessful but instructive attempts, and any published assessments of how close current systems have come to mathematical theory-building in this sense.

Are all odd abundant numbers nearly half-representable by distinct divisors?

Let n be an odd abundant number, that is, $ \sigma(n)>2n, $ where $\sigma(n)$ denotes the sum of the positive divisors of n. Question. Is it true that for every odd abundant number n, there exists a subset S of its positive divisors such that $$ \sum_{d\in S}d=\frac{n+1}{2}\,? $$ For example, the smallest odd abundant number is 945, and $

\frac{945+1}{2}=473=315+105+35+15+3, $ where all five summands are distinct divisors of 945. I was unable to find counterexemples. Indeed, I suspect that a much stronger property holds, and namely that there is a suitable (quite large?) interval centered in $n/2$ of positive integers all representable as a sum of distinct divisors of n. This question is related to pseudoperfect and weird numbers, but differs from the usual subset-sum representation of n by its proper divisors. However a positive answer could give an insight to the longstanding question of the existence (or non-existence) of odd weird numbers.

Amenability of groups in terms of a perturbation condition

Let G be a countable group and $\lambda \colon G \to U(\ell^2 G)$ its left-regular representation. Suppose that there exists a constant $C>0$ such that for all $T \in B(\ell^2 G)$ $$\inf \lbrace\|T-S\| \mid S \in \lambda(G)' \rbrace \leq C \cdot \sup\lbrace \|\lambda(g)T-T \lambda(g) \| \mid g \in G\rbrace.$$ (Here $\lambda(G)'$ denotes the commutant of G in $B(\ell^2 G)$.) Question: Is G amenable? It is fairly easy to see that amenability of G implies the existence of such a constant. Indeed, one may take S to be some fixed point for the conjugation action on $\overline{\rm conv}\lbrace \lambda(g)T\lambda(g)^* \mid g \in G\rbrace$. I am asking for the converse of this statement. EDIT: Since the derivation problem came up in Kate's comment, I want to clarify to what version of it my question is related. The inequality above holds for some C if and only if the first bounded cohomology of G with coefficients in $B(\ell^2 G)$ (with the conjugation action induced by λ) is reduced. This is a straightforward application of the open mapping theorem. Now, two things are unclear: Question: Can $H^1_b(G,B(\ell^2 G))$ be reduced without being zero? and Question: Can $H^1_b(G,B(\ell^2 G))$ be zero without G being amenable?

V3-018439 | MO-52552

Nontrivial finite group with trivial group homologies?

I stumbled across this question in a seminar-paper a long time ago: Does there exist a positive integer N such that if G is a finite group with $\bigoplus_{i=1}^NH_i(G)=0$ then $G=\lbrace 1\rbrace$? I believe this to still be an open problem. For $N=1$, any perfect group (ex: A_5) is a counterexample. For $N=2$, the binary icosahedral group $SL_2(F_5)$ suffices (perfect group with periodic Tate cohomology). And I found in one of Milgram's papers a result for $N=5$, the sporadic Mathieu group M_{23}. Note that this question is answered for infinite groups, because we can always construct a topological space (hence a BG for some discrete group G) with prescribed homologies. Is there another known group with a larger $N\ge 5$ before homology becomes nontrivial? Are there any classifications of obstructions in higher homology groups? [[Edit]]: Another view. A group is $\textit{acyclic}$ if it has trivial integral homology. There are no nontrivial finite acyclic groups. Indeed, a result of Richard Swan says that a group with p-torsion has nontrivial mod-p cohomology in infinitely many dimensions, hence nontrivial integral homology.

Free subgroups vs law

Consider the following two conditions for a group G: (1) G does not satisfy a nontrivial law. (2) G contains a non-abelian free subgroup. Obviously (2) implies (1) and it is easy to construct torsion groups that do not satisfy any law (e.g., the direct product of all finite groups). Thus (1) does not imply (2) in general. However the following question seems open: Are (1) and (2) equivalent for profinite groups? Here is a similar question: Suppose that a residually finite group does not satisfy a law. Does its profinite completion contain a nonabelian free subgroup? These questions may be thought of as possible generalizations of the Tits alternative to residually finite (or profinite) groups. The answer to the second question is positive for finitely generated p-groups. This follows from [Wilson, Zelmanov, Identities for Lie algebras of pro-p groups, JPAA 81(192), 103-109], where the authors prove that if G is a finitely generated residually finite p-group, then either it is finite (and hence satisfies a law), or its profinite completion contains a nonabelian free group. In the general case they only prove that if the profinite completion of a residually finite group does not contain a nonabelian free subgroup, then some Lie algebra associated to the group satisfies a law.

Is every matching of the hypercube graph extensible to a Hamiltonian cycle

Given that Q_d is the hypercube graph of dimension d then it is a known fact (not so trivial to prove though) that given a perfect matching M of Q_d ($d\geq 2$) it is possible to find another perfect matching N of Q_d such that $M \cup N$ is a Hamiltonian cycle in Q_d. The question now is - given a (non necessarily perfect) matching M of Q_d ($d\geq 2$) is it possible to find a set of edges N such that $M \cup N$ is a Hamiltonian cycle in Q_d. The statement is proven to be true for $d \in\{2,3,4\}$.

Comparing the Kazhdan-Lusztig and Steinberg pre-orders

Both Kazhdan-Lusztig and Steinberg have defined pairs of preorders on S_n. Kazhdan and Lusztig's preorders come from their basis: We write $x\leq_L y$ if any left ideal spanned by K-L basis vectors which contains C_y also contains C_x. Similarly for $x\leq_R y$ and right ideals. Note that $x\leq_L y$ if and only if $x^{-1}\leq_R y^{-1}$, so all the information is in one of these preorders. Now, we can define a geometric preorder satisfying similar properties, following Steinberg. Let $\mathfrak{n}$ be the usual strictly upper-triangular matrices in $\mathfrak{sl}_n$ and let $\mathfrak{n}\cap\mathfrak{n}^w$ be its

intersection with itself conjugated by w. We let $x\leq_l y$ if $B\cdot (\mathfrak{n}\cap\mathfrak{n}^y)\subset B\cdot (\mathfrak{n}\cap\mathfrak{n}^x)$, and $x\leq_r y$ if $x^{-1}\leq_ly^{-1}$. Do the preorders $\leq_L$ and $\leq_l$ coincide? It's a theorem (look, for example in Appendix B of Borho and Brylinski, Differential... III) that the equivalence relations induced by them (the left cells) do; they're both distinguished by their Q-symbol under Robinson-Schensted. Do these preorders have a nice description in terms of Robinson-Schensted? EDIT: After speaking with various people, I believe this is an open question, and quite an interesting one in my opinion.

Open problems in Euclidean geometry?

What are some (research level) open problems in Euclidean geometry ? (Edit: I ask just out of curiosity, to understand how -and if- nowadays this is not a "dead" field yet) I should clarify a bit what I mean by "Euclidean geometry". By this term I mean, loosely, the study of the geometry of certain subsets of Euclidean space $\mathbb{E}^n$ from a point of view which is either the "classical" one (i.e. axiomatic), or one that involves more modern tools, but the problem in question has not to be "clearly" a problem within some other branch of maths such as differential or algebraic geometry, algebraic or general topology, analysis, or measure theory. Some examples to clarify: the study of configurations of lines or affine subspaces is EG; but the algebro-topological study of hyperplane arrangements is not. plane conics as defined via their metric property are objects of EG; but "algebraic curves" are not, unless they're defined by some "elementary enough property" (intentionally vague) involving the Euclidean metric. root systems of Lie algebras are EG. polyhedral cones are EG. polytopes are EG. tessellations of space with polytopes or analogous objects are in EG. minimal surfaces in $\mathbb{E}^3$ are not EG. fractal geometry (Julia sets, self-affine fractals...) is not EG. not sure about convex bodies. If they're polyhedral I'd say their study fits in EG. packings of spheres are EG.

What's the Kirby Diagram of a universal $\mathbb{R}^4$?

What's the Kirby diagram of a universal $\mathbb{R}^4$? Background Define $\mathcal{R}$ as the set of smoothings of $\mathbb{R}^4$. For two oriented elements R_1, R_2 in $\mathcal{R}$ we can define their end sum $R_1 \natural R_2$ if we are given two proper embeddings $\gamma_i : [0, \infty) \rightarrow R_i$. We remove a tubular neighborhood of $\gamma_i((0, \infty))$ from each R_i and glue the resulting $\mathbb{R}^3$ boundaries together respecting orientations. The result is the end sum $R_1 \natural R_2$ of R_1 and R_2. As γ_i is unique up to ambient isotopy, $R_1 \natural R_2$ is well defined up to diffeomorphism. In "A universal smoothing of four-space" Freedman and Taylor proved the existence of an element $U \in \mathcal{R}$ such that for any $R \in \mathcal{R}$ the end sum $U \natural R$ is diffeomorphic to U. This U is the universal $\mathbb{R}^4$. Foreground In "An invariant of smooth 4-manifolds" Taylor defines an invariant $\gamma(R) \in \{0,1,2,\ldots,\infty \}$ for $R \in \mathcal{R}$. Taylor defines $\gamma(R)$ to be $sup_K \{ min_X\{ \frac{1}{2} b_2(X) \} \}$, where K ranges over compact 4-manifolds smoothly embedding in R and X ranges over closed, spin 4-manifolds with signature 0 in which K smoothly embeds. (Actually, Taylor defines γ for all smooth 4-manifolds, but we don't need this detail here.) Taylor goes on to prove that if $R \in \mathcal{R}$ and $\gamma(R) > 0$, then any handle decomposition of R has infinitely many three handles. In "4-Manifolds and Kirby Calculus" Stipsicz and Gompf prove, see page 376, that $\gamma(U) = \infty$. Thus, any Kirby Diagram of U must have infinitely many three handles. Question What's the Kirby diagram of a such a U?

Milnor's cartography problem

Let Ω be a round disc of radius $\alpha<\frac{\pi}{2}$ on the unit sphere $\mathbb{S}^2$. It is easy to construct a $(1,\tfrac{\alpha}{\sin\alpha})$-bi-Lipschitz map from Ω to the plane. Is it true that any convex domain Ω' on $\mathbb{S}^2$ with the same area as Ω also admits a $(1,\tfrac{\alpha}{\sin\alpha})$-bi-Lipschitz map to the plane? Comments: This problem appears in Milnor's A problem in cartography. Amer. Math. Monthly 76 1969 1101--1112. I spent quite a bit of time to solve it, but without success. I only noticed that if one exchange "area" above to "perimeter" then the answer is YES. (To prove the statement appy the idea from "A New Area Maximization Proof for the Circle" by Lawlor.)

Card game / options pricing / Brownian bridge question

We play a game. I shuffle a deck of cards and start dealing them face up. After any card you can say "stop", at which point I pay you 1 dollar for every red card dealt and you pay me 1 for every black card dealt. What is your optimal strategy, and how much would you play to pay this game? Clearly the game is worth at least 0, since you can follow the strategy 'wait until all the cards are dealt' and get paid 0. We can conclude that at any stage of the game, we will ask for another card if the expected value of continuing to play is greater than the amount of money already won; otherwise we will say stop. Mathematically, if r is the number of red cards remaining and b is the number of black cards remaining, and $f_{r,b}$ is the expected value of the game at this point, then the expected value of taking another card is $e_{r,b} = \frac{r}{r+b} f_{r-1,b} + \frac{b}{r+b} f_{r,b-1}$ and hence the value of the game at this point, assuming we play the optimal strategy, is $f_{r,b} = \max (\frac{r}{r+b} f_{r-1,b} + \frac{b}{r+b} f_{r,b-1}, b-r)$ with $f_{r,0} = 0$ (if there are only red cards remaining, we have a guaranteed payout of 0) and $f_{0,b} = b$ (if there are only black cards remaining we won't take any more cards). Solving numerically gives an

expected value for this game of 2.624 with 52 cards. I'm interested in what the value is for a deck of $2n$ cards, and if the optimal strategy can be expressed analytically as a function of r and b (ie keep taking cards until you have made $g(r,b)$ dollars, then stop). I've tried changing coordinates to $u=b-r$, $v=b+r$, and I've tried approximating the difference equation as a PDE, but no luck with an analytical solution yet - or even any decent approximations.

Existence of Solutions to an Equation Involving the Sum-of-Divisors Function [Reference Request]

Let $\sigma(x) = \sigma_1(x)$ denote the sum of all the positive divisors of x. If $n \in \mathbb{N}$ is odd and $\gcd(n, \sigma(n)) = 1$, then do there exist any solutions to the following equation? $$2{n^2}\sigma(n) = \sigma({n^2})\sigma(\sigma(n))$$ In other words, does there exist such an odd $N = {n^2}\sigma(n)$ which is also a perfect number? Here, I also list some (open?) problems mentioned by other researchers: (1) Suryanarayana: Is it true that every odd perfect number is of the form $m\sigma(m)$ for some odd integer m; if so, is $\gcd(m, \sigma(m)) = 1$ necessarily? (2) M. V. Subbarao: Does every odd perfect number n (if such exist) have the representation $$n = \frac{1}{2}m\sigma(m) \hspace{0.5in} (*)$$ Another question: Whenever n given by $(*)$ is perfect, does it follow that n is odd and $\gcd(m, \sigma(m)) = 1$? I would appreciate it if anybody could point me to reference(s) to recent results on either Problem (1) or Problem (2).

V3-018449 | MO-57436

A simple question regarding the sum-of-divisors function

A good day to everyone. Consider the following "Conjecture": If $a, b \in M \subset \mathbb{N}$, then $1 < a < b$ and ... [plus some more conditions on a, b and M...] if and only if $\sigma(a) < \sigma(b)$. I have two questions at this point: (1) What properties should elements of the set M have to satisfy this "Conjecture"? (2) What happens to the sets in M if you restrict to the case $\gcd(a, b) = 1$? (Of course, the sets in (1) should have greater asymptotic density than the sets in (2), but can this notion be made more precise?) Now, for the motivation: An example of a set M satisfying this "Conjecture" is any pair (A, B) of relatively prime factors of an odd perfect number given in the Eulerian form $N = {q^k}{n^2}$ (modulo some exceptions), where $\gcd(q, n) = 1$ and $q \equiv k \equiv 1 \pmod4$. Let $$I(x) = \displaystyle\frac{\sigma(x)}{x}$$ be the abundancy index of $x \in \mathbb{N}$. Then by enumerating all possible permutations of the set $$q^k, n, \sigma(q^k), \sigma(n) \in \mathbb{N}$$ we know that exactly one of the following holds (because of $1 < I(q^k) < I(n)$): $$[1] \hspace{0.2in} q^k < n < \sigma(q^k) < \sigma(n)$$ $$[2] \hspace{0.2in} q^k < \sigma(q^k) < n < \sigma(n)$$ $$[3] \hspace{0.2in} n < q^k < \sigma(q^k) < \sigma(n)$$ $$[4] \hspace{0.2in} n < q^k < \sigma(n) < \sigma(q^k)$$ $$[5] \hspace{0.2in} n < \sigma(n) < q^k < \sigma(q^k)$$ Last question: Which of these five "configurations" could we eliminate?

Kronecker Approximation theorem and Fibonacci numbers

There is a famous old theorem by Kronecker that for every positive real α and $\epsilon>0$ there exists a positive integer n such that αn is within ϵ of an integer. Recently I found that the same result is true if we replace αn by αn^2 or any polinomial p such that $p(0)=0$. Could this result be generalised to other functions? Particularly I'm curious about sequences $\alpha 2^n$ and αF_n where by F_n I denote n-th Fibonacci number. Does anyone know anything about it?

Bounds on number of conjugacy classes in terms of number of elements of a group ?

What are bounds on number of conjugacy classes in terms of number of elements of a group ? (I allowed myself to edit the question in spirit of remarkable answers given to it by Gerry Myerson and Geoff Robinson. Below is original text of the question. (Alexander Chervov)). It's about the first step to find an upper bound to the order of a finite group with h conjugacy classes (right or left) that depends only on h. (h a natural non nul integer). I have some doubts about the rigor of my proof that I am sharing with you so that you can help me find a likely error or an omited step. I have attached the scan of my proof to this post. Many thanks

Can you flip the end of a large exotic $\mathbb{R}^4$

Can you flip the end of a large exotic $\mathbb{R}^4$ Background Definition (Exotic $\mathbb{R}^4$): An exotic $\mathbb{R}^4$ is a smooth manifold R homeomorphic but not diffeomorphic to $\mathbb{R}^4$, where $\mathbb{R}^4$ is equipped with its

standard smooth structure. Definition (Large exotic $\mathbb{R}^4$): A large exotic $\mathbb{R}^4$ is an exotic $\mathbb{R}^4$ containing a four-dimensional compact smooth submanifold K' that can not be smoothly embedded into $\mathbb{R}^4$. Definition (End of a large exotic $\mathbb{R}^4$): If R is a large exotic $\mathbb{R}^4$ and D^4 is a four-dimensional disk topologically embedded into R such that $K' \subset D^4$, then $R - D^4$ is an end of R. Remark: The previous definition varies slightly from the standard definition of "end", however it will be used for the remainder of this question. (See Gompf and Stipsicz Exercise 9.4.11 for the standard definition.) Remark: If $R - D^4$ is the end of a large exotic $\mathbb{R}^4$, then $R - D^4$ is a smooth manifold that inherits a smooth structure from R. Definition (Flip of the end of a large exotic $\mathbb{R}^4$): Given $R - D^4$, the end of a large exotic $\mathbb{R}^4$, a flip of $R - D^4$ is a diffeomorphism $f: R - D^4 \rightarrow R - D^4$ that maps the "inner region" of $R - D^4$, that "near" the removed D^4, to the "outter region", that "near infinity", and vica-versa. Remark: The previous definition is also non-standard. I am not aware of any standard definitions that carry, more-or-less, the same meaning. So, at this stage the meaning of the question is hopefully clear. Foreground In our attempt to flip the end of a large exotic $\mathbb{R}^4$ an inconvenient truth stands in our way: Theorem 1 (Uncountably many flips fail): There are uncountably many large exotic $\mathbb{R}^4$'s that one can not flip the end of. Quickly, let us see why this is true. Lemma 9.4.2 along with Addendum 9.4.4 of Gompf and Stipsicz state: Lemma 1: There exist pairs (X,Y) and (L,K) of smooth, oriented four-manifolds with X simply connected, Y and K compact, X and L open (i.e. noncompact and boundaryless), L homeomorphic to $\mathbb{R}^4$, and X with negative definite intersection form not isomorphic to $n\langle-1\rangle$, such that $X - int(Y)$ and $L - int(K)$ are orientation-preserving diffeomorphic. Theorem 9.4.3 of Gompf and Stipsicz states: Theorem: Any L as appears in Lemma 1 is a large exotic $\mathbb{R}^4$. The two statements above lead to: Lemma: One can not flip the end of any L as appears in Lemma 1. Proof: Assume one could flip the end of L. Thus, one could use this flip to glue L to the "end" of X and obtain a simply connected closed smooth four-manifold with negative definite intersection form not isomorphic to $n\langle-1\rangle$. However, according to Donaldson's Theorem (Gompf and Stipsicz Theorem 1.2.30) there exists no such manifold. Thus, there exists no such flip. QED Now we have shown that L can not be flipped. Before we show how uncountably many large exotic $\mathbb{R}^4$'s can not be flipped, we need the definition: Definition (Radial Family): Let R be an exotic $\mathbb{R}^4$. Thus, there exists a homeomorphism $h:\mathbb{R}^4 \rightarrow R$. Define R_t as the image under h of the open ball of radius t centered at 0 in $\mathbb{R}^4$. A radial family is a set of the form $\{R_t | 0 < t \le \infty \}$. Remark: If R_t is a member of a radial family, then R_t is a smooth manifold as it inherits a smooth structure from R Theorem 9.4.10 of Gompf and Stipsicz states: Theorem: If $\{L_t | 0 < t \le \infty \}$ is a radial family for an L as appears in Lemma 1 and r is such that $K \subset L_r$, then $\{L_t | r \le t \le \infty \}$ is an uncountable family of non-diffeomorphic large exotic $\mathbb{R}^4$'s. This leads directly to a proof of Theorem 1. Proof: Assume one could flip the end of L_t for $r \le t \le \infty$, where all notation is as in the previous theorem. Thus, one could use this flip to glue L_t to the "end" of X less the image of $L - L_t$ and obtain a simply connected closed smooth four-manifold with negative definite intersection form not isomorphic to $n\langle-1\rangle$. Again, according to Donaldson's Theorem (Gompf and Stipsicz Theorem 1.2.30) there exists no such manifold. Thus, there exists no such flip.QED Things are seeming rather hopeless at this point. In fact, things are worse than they seem! But, before we can revel in this despair, we must introduce two definitions: Definition (Simply Connected at Infinity): Let Z be a topological manifold. Z is simply connected at infinity if for any compact subset C of Z there exists a compact subset C' of Z that contains C and is such that the inclusion $Z - C' \rightarrow Z - C$ induces the trivial map $\pi_1(Z - C') \rightarrow \pi_1(Z - C)$. Definition (End Sum): Let Z_1 and Z_2 be non-compact oriented smooth four-manifolds that are simply connected at infinity. Choose two proper smooth embeddings $\gamma_i : [0, \infty) \rightarrow Z_i$. Remove a tubular neighborhood of $\gamma_i((0, \infty))$ from each Z_i and glue the resulting $\mathbb{R}^3$ boundaries together respecting orientations. The result is the end sum $Z_1 \natural Z_2$ of Z_1 and Z_2. Remark: The requirement that Z_i is simply connected at infinity guarantees that γ_i is unique up to ambient isotopy and thus $Z_1 \natural Z_2$ is unique up to diffeomorphism (Gompf and Stipsicz Definition 9.4.6). Remark: If R_1 and R_2 are exotic $\mathbb{R}^4$, then they are non-compact oriented smooth four-manifolds that are simply connected at infinity and $R_1 \natural R_2$ is a smooth manifold homeomorphic to $\mathbb{R}^4$. Remark: X of Lemma 1 is simply connected at infinity. Theorem 2: If $\{L_t | 0 < t \le \infty \}$ is a radial family for an L as appears in Lemma 1 and r is such that $K \subset L_r$, where K is as in Lemma 1, then for R an exotic $\mathbb{R}^4$ and t such that $r \le t \le \infty$ there exists no flip of $R \natural L_t$. Proof: The proof is basically a slight variation on the above theme. Assume one could flip the end of $R \natural L_t$ for $r \le t \le \infty$. Thus, one could use this flip to glue $R \natural L_t$ to the "end" of X less the image of $L - L_t$ end summed with R, in other words with the flip glue $R \natural L_t$ to $R \natural (X - (L - L_t))$, and obtain a simply connected closed smooth four-manifold with negative definite intersection form not isomorphic to $n\langle-1\rangle$. Again, according to Donaldson's Theorem (Gompf and Stipsicz Theorem 1.2.30) there exists no such manifold. Thus, there exists no such flip.QED Now we can revel in this despair! However, other ways of creating large exotic $\mathbb{R}^4$'s exist. For example, given a topologically slice knot that is not smoothly slice one can create a large exotic $\mathbb{R}^4$. (See, for example, Davis.) Such a large exotic $\mathbb{R}^4$, as far as I can see, might admit an end flip. But, I'm not sure. Thus, we end where we began. Question Can you flip the end of a large exotic $\mathbb{R}^4$?

A question concerning products of finite cyclic groups

Let $m_1,\ldots, m_n$ be pairwise coprime natural numbers ≥ 1. We consider the product $$G(m_1,\ldots,m_n) := \prod_{i=1}^{n} \mathbb{Z} / m_i \mathbb{Z}.$$ We define $M(n)$ as the set n-tuple of natural numbers ≥ 1 with the property that the entrys are pairwise coprime. We define $l : M(n) \rightarrow \mathbb{N}_0$ by $$l(m_1,\ldots,m_n) = \max_{(x_1,\ldots,x_n) \in G(m_1,\ldots,m_n)} \min \{ k \in \mathbb{N}_0 | x_i+k \neq 0 \forall 1 \leq i \leq n \},$$ hence $l(m_1,\ldots,m_n)$ may be regarded as the maximal distance of the elements of G from the elements which have no identity in their entrys. It is clear, that $l(m_1,\ldots,m_n)$ is always a natural number. The question is now: Does there exist a real number r, such that $r \cdot n \cdot \ln (n) \geq

\sup_{(m_1,\ldots,m_n) \in M(n)} l(m_1,\ldots,m_n)$$ holds for all $n >> 0$ and is it possible to take $r=2$?

Trees in groups of exponential growth

Question: Let G be a finitely generated group with exponential growth. Is there a finite generating set $S \subset G$, such that the associated Cayley graph $Cay(G,S)$ contains a binary tree? Some background: The existence of such a tree clearly implies exponential growth. Kevin Whyte showed in Amenability, Bilipschitz Equivalence, and the Von Neumann Conjecture, Duke Journal of Mathematics 1999, p. 93-112, that such trees exist if G is non-amenable. So the question is only open for amenable groups of exponential growth. One good reason for such a binary tree to exist is the existence of a free semigroup inside G. In fact, if G is solvable, then the existence of such a semigroup is known to be equivalent to exponential growth (and equivalent to being not virtually nilpotent). This is part of some version or extension of the Tits alternative. Grigorchuk constructed an amenable torsion group with exponential growth, which does not contain such a semigroup, but it contains a binary tree. EDIT: Al Tal pointed out in an answer below that Benjamini and Schramm covered the non-amenable case (this is 2. from above) already in Benjamini and Schramm "Every Graph With A Positive Cheeger Constant Contains A Tree With A Positive Cheeger Constant", GAFA, 1997.

Symplectic structures on a homotopy complex projective space

For $n>2$, there are infinitely many differentiable structures on the homotopy type of $\mathbb{C}P^n$. I want to know which differentiable structures support a symplectic form. My question is as follows. Let M be a closed symplectic manifold which is homotopy equivalent to a complex projective space. Can we say that M is homeomorphic or diffeomorphic to the standard one?

Fixed point theorem for convex, closed multivalued mapping

There is well-known fixed point theorem theorem for multivalued l.s.c. maps, based on Michael selection theorem: Suppose, that X is compact, convex and metrizable in locally convex Hausdorff topological vector space. Then any l.s.c. map $F:X\rightarrow X$ which is closed and convex valued has a fixed point, i.e. $x\in F(x)$. The question is, what happens if we drop the assumption that X is metrizable. Xian Wu in his paper "A new fixed point theorem and its application" left it as an open problem, after giving the proof using a metrizability.

Zero divisor conjecture for finite fields

I believe that the most attractive "zero-divisor" conjecture is the existence of non-trivial zero-divisors in a group ring $\mathbb{C}[G]$ for a torsion free group G. For the sake of knowledge let me ask if the zero conjecture is known for finite fields instead of $\mathbb{C}$. More precisely: Let G be a torsion-free group and K be a finite field. Is it true that the group ring $K[G]$ has no non-trivial zero divisors? In particular: Let K be the field with two elements, G be a torsion free group and let $rank(a)$ be the smallest number of elements in the expression of a in the sum $a=\sum g_i$, $g_i\in G$. Is there a constant $R>0$ such that we know for sure that $rank(a)>R$ for every zero-divisor $a\in K[G]$? Here is related question: Group ring and left zero divisor.

The maximum of a polynomial on the unit circle

Encouraged by the progress made in a recently posted MO problem, here is a "conceptually related" problem originating from a 2003 joint paper of Sergei Konyagin and myself. Suppose we are given n points $z_1,...,z_n$ on the unit circle $U=\{z\colon |z|=1\}$ and n weights $p_1,...,p_n\ge 0$ such that $p_1+....+p_n=n$, and we want to find yet another point $z\in U$ to maximize the product $$ \prod_{i=1}^n |z-z_i|^{p_i}. $$ How large can we make this product by the optimal choice of z? Conjecture. For any given $z_1,...,z_n\in U$ and $p_1,...,p_n\ge 0$ with $p_1+...+p_n=n$, there exists $z\in U$ with $$ \prod_{i=1}^n |z-z_i|^{p_i} \ge 2. $$ Here are some comments. If true, the estimate of the conjecture is best possible, as evidenced by the situation where the points are equally spaced on U and all weights are equal to 1. We were able to resolve a number of particular cases; say, that where the points z_i are equally spaced on U, and also that where all weights are equal to 1. The case $n=2$ is almost trivial, but already the case $n=3$ is wide open. In the general case we have shown that the maximum is larger than some absolute constant exceeding 1. Although this is not obvious at first glance, this conjecture is actually about the maxima of polynomials on the unit circle. I would be very interested to see any further progress!

Majorization and Schur Polynomials

Let me first define the majorization order (or dominance order) on partitions as $\lambda \succeq \mu$ iff $$\sum _{i=1}^{k}\lambda_i \geq \sum_{i=1}^{k}\mu_i$$ for all $1\le k\le l-1$ and $$\lambda_1+\cdots+\lambda_l=\mu_1+\cdots+\mu_l.$$ While playing around with some variation on Muirhead's inequality which says that $$m_{\lambda}(x_1,x_2,\dots,x_n)\geq m_{\mu}(x_1,x_2,\dots,x_n)$$ for all $x_i\geq 0$ when $\lambda \succeq \mu$ (here the m_{λ}'s are the monomial symmetric polynomials) I ended up investigating if such an inequality holds for Schur polynomials, which are another famous basis of the ring of symmetric functions. I tried a few special cases, and the following seems to hold, but I don't have a proof or a counterexample. So the question is: Let $x_1,\dots,x_n \geq 0$ and $\lambda\succeq \mu$, is it always true that $$\frac{s _{\lambda}(x _1,x _2,\dots,x _n)}{s _{\lambda}(1,1,\dots,1)}\geq \frac{s _{\mu}(x _1,x _2,\dots,x _n)}{s _{\mu}(1,1,\dots,1)}?$$ If not, does majorization induce some similarly nice order on values of Schur polynomials?

Motivation for uniform surjectivity of mod l representations associated to elliptic curves

Background Let E be an elliptic curve over $\mathbb{Q}$ and let $G_{\mathbb{Q}}$ be the absolute Galois group $Aut(\overline{\mathbb{Q}})$. For any positive integer n the n-torsion subgroup $E[n](\overline{\mathbb{Q}})$ is stable under the $G_{\mathbb{Q}}$-action. Since $E[n](\overline{\mathbb{Q}})$ is isomorphic to $(\mathbb{Z}/n\mathbb{Z})^2$ one gets a continuous (with respect to the profinite topology on the left and the discrete on the right) homomorphism $$ \overline{\rho_{E,\, n}}\colon G_{\mathbb{Q}} \to GL_2(\mathbb{Z}/n\mathbb{Z}) $$ which one calls the mod n representation associated to E. As n varies these are compatible and taking limits gives representations $\rho_{E,\ell^{\infty}}$ and ρ_E with values in $GL_2(\mathbb{Z}_l)$ and $GL_2(\widehat{\mathbb{Z}})$ which one calls respectively the ℓ-adic and adelic representations associated to E. Alternatively, $\rho_{E,n}$ is isomorphic to the representation induced by the action of $G_{\mathbb{Q}}$ on the etale cohomology $H^1_{\text{et}}(E_{\overline{\mathbb{Q}}}; \mathbb{Z}/n\mathbb{Z})$; the description of $\rho_{E,n}$ via torsion generalizes to give representations $\rho_{A,n}$ for higher dimensional abelian varieties, but for a general variety one must instead use cohomlogy. Serre famously proved that for E an elliptic curve with $End(E) = \mathbb{Z}$, $\rho_E(G_{\mathbb{Q}})$ has finite index in $GL_2(\widehat{\mathbb{Z}})$. In particular for ℓ large $\rho_{l^{\infty}}$ is surjective; how large one must take ℓ depends on E. Conjecture This last fact does not depend on E. I.e. there exists a constant N such that for every $E/\mathbb{Q}$ with $End(E) = \mathbb{Z}$ and $\ell \geq N$, the mod ℓ representation $\overline{\rho_{E,\ell}}$ is surjective; equivalenty there is an upper bound (independent of E) on the index of $\rho_E(G_{\mathbb{Q}})$. By a recent paper of Bilu and Parent, one knows that the image is either surjective or contained in a non-split cartan subgroup. My Question Why do people expect this to be true? Does it follow from other believable conjectures? Is there some heuristic that predicts this? One fact is that one can phrase this question as the failure of various modular curves (e.g. $X_{ns}(l)$, which have increasingly large genus) to have non-trivial rational points. Is there a geometric reason that one expects these modular curves to have no non-trivial rational points?

Series whose convergence is not known

For most of the mathematical concepts I learn, it has more or less always been possible to find (at least google and find) unsolved problems pertaining to that specific concept. Keeping a bag of unsolved problems on most topics I know has been to my benefit in that it reaffirms me that mathematics is a thriving subject. Coming to point, I am unable to find an elementary series of the kind we know on real analysis courses whose convergence is an unsolved problem. Please, share if you have any. Thanks.

Convex hull in CAT(0)

Let X be complete $\mathop{CAT}(0)$-space and $K\subset X$ be a compact subset. Is it true that convex hull of K is compact? Comments: Convex hull of K = intersection of all closed convex sets containing K. The space is NOT assumed to be locally compact This problem was mentioned in 6.B$_1$(f) of Gromov's "Asymptotic invariants of infinite groups" (1993). I believe there is a counterexample, maybe even in case of negatively pinched curvature (in the sense of Alexandrov).

A toy model for the t-section problem

Let $S(x)$ be the area of the yellow curvilinear triangle. I'd like to find a graph for which $S(x)=H(x)$ where $H $ is some prescribed function (small, smooth, vanishing near the endpoints to any order you wish, etc.). Is it always possible or there are some non-obvious hidden restrictions? alt text http://www.artofproblemsolving.com/Forum/latexrender/pictures/b/4/6/b46dbb397d96f17cce1e421bfaf29b9a80d26c81.png The question comes from the infamous t-section problem (if you know the areas of all sections of a symmetric convex body by the hyperplanes at some fixed small distance t from the origin (so small that all sections are non-empty), can you recover the body?). The problem is open even on the plane. I do not say that this toy question is directly relevant here but an answer to it will certainly make a few things clearer for me.

What is known about polyhedra nets that allow overlapping?

It is an open problem that the net of any convex polyhedron can be unfolded onto a flat plane with no overlapping. Is anything known if we allow x faces to overlap? For example, is it known if any convex polyhedron can be unfolded with a maximum of 2 faces overlapping? What about the more general case of a polyhedron that is topologically convex (that is, its graph is isomorphic to the graph of a convex polyhedron)? This paper provides an example of an open polyhedron without a net that is topologically convex, and the closed case appears to be taken care of by this paper (mentioned in an answer below). One solution to the topologically convex case would then to be to find a procedure to modify either polygon so that the number of overlapping sides increases without bound. I have been unable to do so without breaking the topologically convex property, but it seems a reasonable task.

Shortest closed curve to inspect a sphere

Let S be a sphere in $\mathbb{R}^3$. Let C be a closed curve in $\mathbb{R}^3$ disjoint from and exterior to S which has the property that every point x on S is visible to some point y of C, in the sense that the segment xy intersects S at precisely the one point x. I am interested in the shortest C with this property. In computational geometry, such paths are called watchman tours, and there are many results concerning polygons in the plane finding such tours. This question arose at a conference I'm attending, and I was pointed to a paper by V. A. Zalgaller: "Shortest Inspection Curves for the Sphere" (Journal of Mathematical Sciences, Volume 131, Number 1, 5307-5320; Translated from Zapiski Nauchnykh Seminarov POMI, Vol. 299, 2003, pp. 87-108.) I cannot access the paper from the conference, but from the abstract it appears he focused on open rather than closed curves. Has anyone heard of this natural question? Can you point me to relevant literature? Thanks! Addendum. Here is the 4π saddle / baseball-stitches curve suggested by Gjergji Zaimi:

When shorter means smaller?

Assume a convex figure $F\subset \mathbb R^2$ satisfies the following property: if $f:F\to \mathbb R^2$ is a distance-non-increasing map then its image $f(F)$ is congruent to a subset of F. Is it true that F is a round disk? Comments: It is easy to see that the round disk has this property. One can reformulate the property: if for some set $G\subset\mathbb R^2$ there is a distance-non-contracting map $G\to F$ then there is a distance-preserving map $G\to F$. (The equivalence follows from Kirszbraun's theorem) Some figures, such as the Reuleaux triangle are bad (see the comments below). The construction with two folds along parallel lines kills many examples, in particular, the following figure: the intersection of two discs, say the unit disc with center at (0,0) and the disc of radius 1.99 and center at (0,1) --- see the comments by Martin M. W. below. This construction also gives the following: If F is good then for any point $x\in \partial F$ the restriction of $\textrm{dist}_x$ to ∂F has no local minima other than x. (This property holds for any convex figure C^2-close to a round disc.) This problem was meant to be an exercise for school students, but I was not able to solve it :). It appeared in print in 2008 (in Russian), see Problem 5 in Плоское оригами и длинный рубль. One answer is accepted, BUT it only provides a solution for unbounded figures.

Convex bodies with constant maximal section function in odd dimensions

In 1970 or so, Klee asked if a convex body in $\mathbb R^n$ ($n\ge 3$) whose maximal sections by hyperplanes in all directions have the same volume must be a ball. The counterexample in $\mathbb R^4$ is trivial and can be described as follows: Let $f:[-1,1]\to\mathbb R$ be continuous, strictly concave and satisfy $f(-1)=f(1)=0$. For every such function, let Q_f be the body of revolution given by $y^2+z^2+t^2\le f(x)^2$. Then Q_f and Q_g have the same maximal sections in every direction if (and, actually, only if) f and g are equimeasurable, i.e., $|\{f>t\}|=|\{g>t\}|$ for all $t>0$. (Of course, there are plenty of concave functions equimeasurable with $\sqrt{1-x^2}$). With some extra work, one can construct something like this in $\mathbb R^n$ when n is even though I do not know any similarly nice geometric description of such bodies for $n\ge 6$. What I (and my co-authors) are currently stuck with is the case of odd n (say, the usual space $n=3$). In view of such simple example in $\mathbb R^4$, I suspect that we are just having a mental block. Can anybody help us out?

Totally rational polytopes

Define a convex polytope in $\mathbb{R}^d$ as totally rational (my terminology) if its vertex coordinates are rational, its edge lengths are rational, its two-dimensional face areas are rational, etc., and finally its (positive) volume is rational. So: rational coordinates, and the measure of every k-dimensional face, $1 \le k \le d{-}1$, is rational, and the d-dimensional volume is positive and rational. (Scaling could then convert all these rationals to integers.) For example, the hypercube with vertex coordinates $\{0,1\}^d$ is totally rational. Similarly an axis-aligned box with integral vertex coordinates is totally rational. Q1. Are there other classes of totally rational polytopes, classes defined for all d? In particular, Q2. Do there exist totally rational simplices in $\mathbb{R}^d$ for arbitrarily large d? Pythagorean triples yield totally rational triangles. I am not even certain that the Heronian tetrahedra described in this MathWorld article are totally rational, because it is unclear (to me) if they can be realized with rational vertex coordinates. All this is likely known, in which case key search phrases or other pointers would be welcomed. Thanks! Addendum. Gerry Myerson's useful summary of Problem D22 in Unsolved Problems In Number Theory answers Q2: The problem is open! Q1 remains (apparently) interesting; see the comments by Steve Huntsman and Gerhard Paseman.

Once differentiable, piecewise degree three polynomials on triangulated planar domains

Here is an easily described, but very difficult, problem that I (and a number of other people) really would like to see solved during our life times. The basic problem is to compute the dimension of a certain vector space. Suppose we are given a triangulation (a tessellation by triangles where any two triangles share at most a common edge or a common vertex) of a polygonal domain in the plane. Let S be the space of once differentiable functions on that triangulation that on each triangle can be represented as a bivariate polynomial of degree 3. S is clearly a vector space. It is known that the dimension of that space is greater than or equal to $3V_B + 2V_I + 1 + \sigma$ where V_B is the number of boundary vertices, V_I is the number of interior vertices, and σ is the number of singular vertices of the underlying triangulation. A singular vertex is an interior vertex that has exactly four edges attached where those edges form two parallel pairs. (In other words, a singular vertex is the intersection of the diagonals of a convex quadrilateral.) It is known that generically the dimension of S equals the given expression, and there is no case known where the dimension is larger than that expression. Many people conjecture that the lower bound equals the dimension for all triangulations. Prove, or disprove, that conjecture. Some background: triangulations are the natural generalization of a partition of an interval to two variables, and S is a spline space with potential for a wide range of practical problems, such as data fitting or solving partial differential equations. The problem has been known among approximation theorists since the early 1970s, and despite efforts by a number of people the problem is still unsolved. For more information on spaces like S see the recent book by Lai and Schumaker [Spline Functions on Triangulations, Cambridge University Press] in particular section 9.9. The basic issue with the kind of spline space considered here is that the dimension depends not just on the topology of the triangulation, but also on its geometry. An arbitrarily small change of the location of the vertices can change the dimension. If the polynomial degree is four (instead of three) it is known that the dimension can change only when a vertex switches between being singular and non-singular. On the other hand, if the polynomial degree is two (instead of three) many configurations other than singular vertices are known where the dimension changes with the geometry. So the polynomial degree three straddles the boundary, and we would like to know to which camp it belongs.

Complex vector bundles that are not holomorphic

Is there an example of a complex bundle on $\mathbb CP^n$ or on a Fano variety (defined over complex numbers), that does not admit a holomorphic structure? We require that the Chern classes of the bundle are (k,k) Hodge classes (which is automatic for $\mathbb CP^n$ or Fanos of dimension<4). If by any chance such examples are known, what is the smallest dimension of the variety (or the bundle)? For $\mathbb CP^1$ it is elementary to see that all bundles are holomorphic. In the book of Okonek and Schneider it is stated, that all complex bundles on $\mathbb CP^2$ and $\mathbb CP^3$ are also holomorphic. But for $\mathbb CP^n$, $n\ge 4$ this is stated as an open problem (as for 1980).

What is the degree of a symmetric boolean function?

(previous title " Zero sum of binomials coefficients - a stronger version ") This is a stronger version of another question. Is there an $N\in \mathbb N$ and a sequence of non-constant functions $ \left\{ p_n:[n] \to \{ 1,-1 \} \right\}_{n=N} ^{\infty}$ such that for all $n>N$ we have: $$ \sum _{i=0} ^{n} (-1)^{i} p_n(i) \cdot \binom {n} {i} = 0$$ For instance, for all odd values of n, we may choose $p_{n}(i)=\begin{cases} (-1)^{i} & i\leq\frac{n-1}{2}\\\ (-1)^{i+1} & i\geq\frac{n+1}{2}\end{cases}$. This simply means we sum the first half of the binomial coefficients and subtract the second half. The fact that for odd values we can partition the set of binomial coefficients evenly allows us to do that, so I don't see how the same trick may be applied for even values. To my understanding, the methods that solved the previous question (for which I thank darij grinberg and Mikael de la Salle) are not applicable here. My guess, as before, is that there is no such sequence (in which all functions are non-constant), any ideas on how to prove it? (a counter example would surprise me, but is of interest as well)

The quaternion moat problem

"One cannot walk to infinity on the real line if one uses steps of bounded length and steps on the prime numbers. This is simply a restatement of the classic result that there are arbitrarily large gaps in the primes." So begins the paper by Gethner, Wagon, and Wick, "A Stroll Through the Gaussian Primes" (American Mathematical Monthly 105(4): 327-337 (1998).) They explain that it is unknown if one can walk to infinity on the Gaussian primes with steps of bounded length. Paul Erdős was reported to have conjectured this is possible ("A conjecture of Paul Erdős concerning Gaussian primes." Math. Comp 24: 221-223 (1970); PDF). Later Erdős is reported to have conjectured the opposite: that no such walk-to-∞ is possible [GWW98, p.327]. This has become known as the Gaussian moat problem, apparently still unresolved. My question is: Is there an analogous quaternion moat problem? Is it solved? open? Is it easier or harder than the Gaussian moat problem? Define a nonzero quaternion $q = a + bi + cj + dk$ as prime iff (a) it is a Hurwitz quaternion (all components integer, or all components half-integer) and (b) its norm $a^2 + b^2 +c^2 + d^2$ is prime. (Part (b) is a consequence of the inability to factor q; see, e.g., Theorem 15 in *"A proof of Lagrange's four square theorem using quaternion algebras." Drew Stokesbary, 2007; PDF, DOI: 10.2139/ssrn.2396123). Can one "walk-to-∞" on the quaternion primes using steps of bounded length? Perhaps relevant here is Lagrange's four-square theorem, which states that any natural number can be represented as the sum of four squares. I ask this question in relative naïveté, and appreciate being enlightened.

Exact consistency-strength of "all projective sets are Ramsey"

I wonder if the exact consistency strength of "All projective sets have the Ramsey property" is still open. In Solovay's model, all sets have the Ramsey property, so the consistency strength of this is below an inaccessible. As far as I know, there are some implications under forcing axioms. And all sets up to a certain level of the projective hierarchy having the Ramsey property is still do-able from just ZFC. But I can't seem to find anything which shows Solovays inaccessible is really necessary in case of the Ramsey property (like Raisonnier/Shelahs result for Lebesgue measure), or oppositely, that you can get a model where "All projective sets have the Ramsey property" from just ZFC (like for the Baire property).

Convergence speed of Jacobi eigenvalue algorithm for parallel ordering(Brent-Luk) ?

Is there estimate for convergence of the Jacobi eigenvalue algorithm for Hermitian matrices for "parallel ordring" (Brent-Luk ordering (see comment below)) ? For example for 4 4 matrices parallel ordering is the following 1a) 12 1b) 34 2a) 23 2b) 14 3a) 13 3b) 24 [EDIT] Moreover convergence itself is not known for such ordering even in 4x4 case. I have consulted with many experts in the field - it is not proved. Numerical simulations (checked more than 10^10 matrices of different form) shows that the convergence exists. There is certain subtlety in the definition of method. Which lead some authors to claim that there is NO convergence. But actually counter-example is not for "reasonable" implementation of details. The detail is the following consider 2x2 matrix such that diagonal elements are equal. Then the rotation can be either +45 either -45 - no unique choice. What the authors claim that if we have a freedom to choose +45 or -45 by our own wish, in each step where ambiguity occurs - then there will be counterexample ! However this counter-example does NOT work if we fix +45 (or -45) once and forever ! I.e. in the case of ambiguity we ALWAYS choose angle to be the same. Simulations shows - that than there is no problem. I spent about 2 weeks trying to prove this just in the 4x4 example - but I was unable to prove it. The difficulty is that we need to analyse about 3-4 sweeps. It can be shown that there always exists a matrix that can be arbitrary "BAD" after 1-2 sweeps... [END of EDIT on 21 Jan. 2012] As far as I can expect that there should be ultimate quadratic convergence [EDIT] actually as works of Walter F. Mascarenhas suggests their will be cubic ultimate convergence[EDIT] but I

am interested at the first iteration - they should be at most linear convergence, but it is not clear for is there uniform convergence speed or there can be some matrices where convergence can be arbitrary bad ? (From simulation we see that probably there is NO bad examples - convergence seems rather fast, but there are certain difficulties in proving this theoretically). Actually even the convergence for arbirary ordering is not clear for me. Paper by Walter Mascarenhas: SIAM. J. Matrix Anal. & Appl. 16, pp. 1197-1209 (13 pages) On the Convergence of the Jacobi Method for Arbitrary Orderings Walter F. Mascarenhas States only convergence of the diagonal elements. Non-diagonal elements may not converge, for some sophisticated orderings. He constructed examples in his PhD at MIT unpublished (private communication from him)

What is known about Ulam's problem of metric spaces with isometric squares?

Background In the book Problems in Modern Mathematics, S. Ulam asks the following question: Suppose A and B are metric spaces, such that A^2 and B^2 equipped with the 2-metric $d((x_1, y_1),(x_2, y_2)) = \sqrt{d(x_1, x_2)^2 + d(y_1, y_2)^2}$ are isometric. Does it follow that A and B must also be isometric themselves? The answer to this general question is negative. Take for example the space of the rational numbers $\mathbb{Q}$ and the space $\mathbb{Q} \sqrt{2}$ of rational multiples of $\sqrt{2}$. These two spaces are obviously not isometric, but their squares are, isometry being just the rotation by $\frac{\pi}{4}$. See http://www.ams.org/journals/proc/1971-029-03/S0002-9939-1971-0278262-5/S0002-9939-1971-0278262-5.pdf for the proof. Question What is the status of this problem for slightly less general metric spaces? I am especially interested in the following cases: What is known about this problem for complete metric spaces? What is known for finite metric spaces? A good survey if it exists would be more than welcome.

Compact surfaces smoothly immerse in: $\mathbb{R}^4$ or $\mathbb{R}^5$?

I wonder if someone can clarify whether it is known that every closed, orientable surface (2-manifold) has a smooth isometric immersion in $\mathbb{R}^4$? This topic has been discussed rather thoroughly in the earlier MO question, "Nash embedding theorem for 2D manifolds." However, I am puzzled by two claims that seem at odds, but are surely not-rather I just don't understand the terminology. First, Gromov established that every compact surface has a smooth embedding in $\mathbb{R}^5$. This is from his 1986 book, Partial Differential Relations. See the above MO question for a quote. Second, as user jc said, "Poznyak proved that $\mathbb{R}^4$ works for any compact part of a complete surface." Here is a more precise statement of Poznyak's result, from the book by Jia-Xing Hong, Isometric embedding of Riemannian manifolds in Euclidean spaces (p.40): Theorem 2.3.1. Let g be a smooth complete metric defined in $\mathbb{R}^2$. Then for any compact set Ω in $\mathbb{R}^2$, (Ω,g) admits a smooth isometric immersion in $\mathbb{R}^4$. Since Poznyak's $\mathbb{R}^4$ result is from 1973, and Gromov's $\mathbb{R}^5$ from 1986, it must be that Poznyak's theorem does not improve Gromov's to $\mathbb{R}^4$. Is this because "a compact part of a complete surface" is not the same as a "compact surface"? Can anyone explain this to me? Thanks! E.G. Poznyak, "Isometric immersions of two-dimensional Riemannian metrics in Euclidean space." Russian Math. Surveys, 28:4 (1973), pp. 47-77. Uspekhi Mat. Nauk, 28:4 (1973), pp. 47-76. Answered. Robert Bryant resolved my confusion: "A compact surface without boundary can't be identified with a subset of the plane." It is my understanding now that it remains an open question of whether or not every compact surface (without boundary) has a smooth immersion in $\mathbb{R}^4$: neither Gromov's nor Poznyak's results settle this question, and as far as I know there is no known counterexample. I'm adding the open-problem tag, because although Robert completely answered my specific question, the question suggested by the title is open.

What is the maximal density vertex subset of the 8-connected grid with induced vertex degrees ≤ 4?

Let G be the infinite graph defined by 8-connection of $\mathbb{Z}^2$. What is the maximal density vertex subset whose induced subgraph has maximum degree ≤ 4? More precisely, what is the maximal density $\delta(4)$ as defined in this paper which gives the bounds $\frac{3}{5} \leq \delta(4) \lt \frac{5}{8}$? This question could be known to be open, and it has been asked on math stackexchange. To make this question less dry I am adding an example of a periodic tiling which meets the $\frac{3}{5}$ lower bound, and additional tilings with this density are given in the paper linked above. I do not know if a pattern has been found with a higher density subject to the degree constraint, or whether the strictness of the $\frac{3}{5}$ bound has been proved. . . X X X . . X X X X X . . Irreducible polynomials with constrained coefficients

Over at the Cafe, after reading about TWF 285, I asked more-or-less About how many polynomials with coefficients in $\{\pm 1\}$ and of degree d are irreducible? and that's what I want to ask here. The first no-go analysis: since if P is reducible, then it is reducible mod 3, we get that the number of reducible such is $O(\frac{d-1}{d}3^d)$; but that's clearly too large already to help much; reducing mod 2 we can't distinguish polynomials anymore!

Diameter of universal cover

Let M be Riemannian manifold and $\tilde M$ be its universal cover (with induced metric). What is the upper bound for $k=\mathop{diam}\tilde M/\mathop{diam} M$ in terms of $m=|\pi_1(M)|$ (or $\pi_1(M)$)? Comments: There is a similar answered question here, but there cover is NOT universal. So we get $k\leqslant m$, but $k\ll m$ is expected. The question is open even in case $\pi_1=\mathbb Z_m$ (even asymptotics is not known). Clearly, $\sup k$ for given finite group $\Gamma=\pi_1(M)$ is an invariant of Γ. Is it an interesting invariant? Examples: For $\pi_1=\mathbb Z_{3\cdot 2^n}$ one can make $k\sim n$ or $k=O(\log m)$ (see my answer below). For $\pi_1=S_n$, one can make k of order n^2 or (see Greg's answer and also this question). It is much more than $\log m$, but still $k=o(\log^2 m)$.

Given a lattice L with n elements, are there finite groups H < G such that L $\cong$ the lattice of subgroups between H and G?

If there is no restriction on n, this is a famous open problem. I'm wondering if any recent work has been done for small $n>6$. I believe the question is answered (positively) for $n=6$ by Watatani (1996) MR1409040 and Aschbacher (2008) MR2393428. I also believe we can answer it for $n=7$, with one possible exception. The exceptional case is shown below. So my two questions are these: Does anyone know of recent work on this special case of the problem (specifically for $n=7$ or $n=8$)? Has anyone found a finite group G with a subgroup H such that the interval $[H, G] = \{K : H \leq K \leq G \}$ is the lattice shown above? If not, I'd be happy to hear if anyone has ideas about how we might prove that such a group exists (without necessarily producing the group). Or, if you can put restrictions on such a group, that might be useful. For example, I believe I can show that there is no finite solvable group with this property. (By the way, I have searched many of the groups in GAP's small groups library, and this was helpful for finding some of the other difficult 7-element cases.) Correction: We don't really have an answer to this question for $n=7$. Rather, we can show that every lattice with at most 7 elements (except possibly the one above) is the congruence lattice of a finite algebra. Pálfy and Pudlák MR593011 showed the two questions are equivalent when n is not restricted, but their proof doesn't go through for fixed n. Nonetheless, we can prove that a (minimal) finite algebra with the lattice above as congruence lattice must be a transitive G-set (modulo constant operations), so the existence of such a finite algebra is equivalent to the existence of finite groups H < G with [H,G] isomorphic to the lattice above. (This is the reason I phrased my question in terms of subgroup lattices.) Update: (2012/02/22) If the interval $[H,G]$ is the lattice above, with H core-free, I believe I can prove that a minimal normal subgroup of G must be non-abelian, which isn't much, but it's a start! In particular, I think it rules out the affine case of the Aschbacher-O'Nan-Scott Theorem.

Are the C(S^n, S^n)'s homeomorphic ?

Let m, n > 1. Is it true that C(S^m, S^m), and C(S^n, S^n) are homeomorphic ? [both endowed with the sup metric (or equivalently the compact-open topology)] Generally, C(S^n, S^n), with n >= 1, is a countably infinite (disjoint) union of path-connected (due to Hopf) components C_{n,k}, k in Z. I think each of these components may be viewed as an infinite dimensional Frechet manifold. Unfortunately, they are not contractible. However, the question is [somewhat vaguely] motivated by the Henderson's Theorem. Also, I have some related questions : - Fixing n, are the C_{n,k}'s homeomorphic to each other (at least for k <> 0) ? - Are there some m, n, k, l with m <> n s.t. C_{m,k} ~ C_{n,l} ? What I was able to do in this direction until now is to show the existence of a proper, one-to-one, degree-preserving map from C(S^m, S^m) into C(S^n, S^n). Even for m >> n, but far to be surjective.

Are acyclic subcomplexes of finite contractible 2-complexes contractible?

Let Y be a contractible finite simplicial 2-complex. Let X be an acyclic subcomplex of Y (i.e. X connected, $H_1(X)=0$, $H_2(X)=0$). Is X contractible? (Equivalently, is $\pi_1(X)$ trivial?) I asked this question among others here before, but it remained unanswered. Apparently this question is equivalent to the following one. If $m < n$, $G = \langle a_1,\dotsc,a_m \mid r_1 = \dotsb = r_m =1 \rangle$ and $J=\langle a_1,\dotsc,a_n \mid r_1 = \dotsb = r_n =1 \rangle$ are two groups given by (balanced) presentations, the presentation of G is a sub-presentation of the presentation of J, and J is trivial, is G trivial? (It can be shown that the abelianization of G is trivial.)

Die-rolling Hamiltonian cycles

Let R be a rectangular region of the integer lattice $\mathbb{Z}^2$, each of whose unit squares is labeled with a number in $\lbrace 1, 2, 3, 4, 5, 6 \rbrace$. Say that such a labeled R is die-rolling Hamiltonian, or simply rollable, if there is a Hamiltonian cycle obtained by rolling a unit die cube over its edges so that, for each square $s \in R$, the cube lands on s precisely once, and when it does so, the top face of the cube matches the number in s. For example, the 4×4 "board" shown below is rollable. Q. Is it true that, if R is die-rolling Hamiltonian, then the Hamiltonian cycle is unique, i.e., there are never two distinct die-rolling Hamiltonian cycles on R? This "unique-rollability" question arose out of a problem I posed in 2005, and was largely solved two years later, in a paper entitled, "On rolling cube puzzles" (complete citation below; the 4×4 example above is from Fig. 17 of that paper). Although the original question involved computational complexity, the possible uniqueness of Hamiltonian cycles is independent of those computational issues, so I thought it might be useful to expose it to a different community, who might bring different tools to bear. It is known to hold for R with side lengths at most 8. If not every cell of R is labeled, and unlabeled cells are forbidden to the die, then there are examples with more than one Hamiltonian cycle. Edit1. Rolling a regular tetrahedron on the equilateral triangular (hexagonal) lattice is not as interesting. See the Trigg article cited below. Edit2. Serendipitously, gordon-royle posted a perhaps(?) relevantly related question: "Uniquely Hamiltonian graphs with minimum degree 4." The computational version is Open Problem 68 at The Open Problems Project. "On rolling cube puzzles." Buchin, Buchin, Demaine, Demaine, El-Khechen, Fekete, Knauer, Schulz, Taslakian. Proceedings of the 19th Canadian Conference on Computational Geometry, Pages 141-144, 2007. PDF download. Charles W. Trigg. "Tetrahedron rolled onto a plane." J. Recreational Mathematics, 3(2):82-87, 1970.

Example of a compact Kähler manifold with non-finitely generated canonical ring?

A celebrated recent theorem of Birkar-Cascini-Hacon-McKernan and Siu says that the canonical ring $R(X)=\oplus_{m\geq 0}H^0(X,mK_X)$ of any smooth algebraic variety X over $\mathbb{C}$ is a finitely generated $\mathbb{C}$-algebra. On the other hand P.M.H. Wilson (using a construction of Zariski) gave an example of a compact complex manifold X with $R(X)$ not finitely generated. However his manifold X is not Kähler. Does anyone know an example of a compact Kähler manifold X with $R(X)$ not finitely generated? Or is this an open problem?

Reference Request - Jakob Weisblat's "The Search for the Odd Perfect Number"

Hi All! I am currently trying to locate an online copy of Jakob Weisblat's paper titled "The Search for the Odd Perfect Number". I could only get hold of the abstract: "A perfect number is a number whose proper divisors add up to the number itself. All known perfect numbers are of the form $(2^{p}-1)(2^{p-1})$ where p is prime and $2^{p}-1$ is prime. This talk will consider the possibility of an odd perfect number. After considering criteria for the prime factorization of an odd perfect number, many categories of odds will be eliminated. The remaining categories will then be more thoroughly considered. The first part of the talk will be my personal research and investigations without having looked at anyone's previous work. Next, interesting previous studies on this matter will be discussed. Finally, my personal work will be compared to the previous analyses, and my research will be extended using this new information." If anybody out there has a copy or has a web-link to an online copy, would you please be willing to share it? Thanks! Edit: After taking to Ivars Peterson of MAA, it appears that the author was not required to make a paper submission for his talk. Likewise, the author does not have a publicly available e-mail address. Hence, reflecting quid's suggestion, is a write-up of the author's notes for this talk available somewhere? The author is currently unreachable through Facebook messaging.

Number of valid topologies on a finite set of n elements

I've heard that the problem of counting topologies is hard, but I couldn't really find anything about it on the rest of the internet. Has this problem been solved? If not, is there some feature that makes it pretty much intractable?

Is S^2 x S^4 a complex manifold?

As observed by Calabi a long time ago, the manifold $S^2\times S^4$ admits an almost-complex structure (obtained by embedding it in $\mathbb{R}^7$ and using the octonionic product), which however is not integrable. Is it known whether $S^2\times S^4$ admits an integrable complex structure? A few remarks. This is stated as an open problem in Calabi's paper, but perhaps it has been solved in the meantime? This is similar to the case of S^6, which is still open (see this question). One can also ask the same question for $\Sigma\times S^4$ for Σ any compact Riemann surface It seems that some people believe that every almost-complex manifold of real dimension 6 or more admits an integrable complex structure (see this other question). Even more generally (and this is obviously still open), one can ask about an arbitrary finite product of even dimensional spheres (excluding S^0). It is known that this is almost complex iff the only factors that appear are S^2, S^6 and $S^2\times S^4$. If one allows connected sums, then for example $(S^2\times S^4)\#2(S^3\times S^3)$ is a complex manifold, and in fact it has complex structures with trivial canonical bundles (see for example here and here).

When is the norm of all positive operators on an ordered Banach space determined by their values on the positive cone?

I'm trying to investigate the interplay between the norm and cone of positive elements in ordered Banach spaces. In particular, I would like a nice characterization of when the norm of a positive operator can be obtained as a supremum of norms over all norm 1 positive elements (see 1. below). It is easy to show that this always holds for Banach lattices, but gets tricky when trying to prove this more generally. To be a bit more detailed, let X be a Banach space with a cone (or wedge) of 'positive' elements, denoted by X_{+}; X is then called an ordered Banach space and $x\leq y$ means $y-x\in X_{+}$. I will call X_{+} generating if $X=X_{+}-X_{-}$; proper if $X_{+}\cap(-X_{+})=\{0\}$; and normal if $0\leq x\leq y$ implies $\|x\|\leq\|y\|$. A bounded linear operator $T:X\to X$ is called positive, if $x\geq 0$ implies $Tx\geq 0$. An ordered Banach space with the property that every positive operator satisfies $$\|T\|=\sup\{\|Tx\|:x\in X_{+},\|x\|=1\}$$ I will say has the positive operator property, i.e., the norms of positive operators are completely determined by their behavior on the cone. My question is: Let X be an ordered Banach space with a closed, proper, generating, normal cone. Is there a characterization of the positive operator property in terms of the cone-norm interaction? Thus far I have found a few sufficient conditions: For all $x\in X$ there exist $X\ni x_{1},x_{2}\geq0$ such that $x=x_{1}-x_{2}$ and $\|x_{j}\|\leq\|x\|$ for $j=1,2$. For all $x\in X$ and $X\ni a,b\geq0$, $-a\leq x\leq b$ implies $\|x\|\leq\max \{ \|a\|,\|b\| \}$. together imply the positive operator property. Another sufficient condition is having the property that for any $x\in X$ it holds that $\|x\| = \inf \{\|z_+ + z_-\|:z_\pm \geq 0;x=z_+ -z_-\}$. Being a Banach lattice is sufficient to have this property (by invoking the property $\|x\|=\||x|\|$), but seems to be a bit more general since $\mathbb{R}^3$ with the Euclidean norm and the `ice-cream cone' $\{(x_1,x_2,x_3):x_1\geq (x_2^2+x_3^2)^{1/2} \}$ (which is not a lattice) also has this property (so being a lattice is not necessary for the positive operator property). I've been unable to prove that any of these conditions are necessary. The last one had been my best bet so far, but I'm beginning to doubt the existence of a nice list of conditions on the norm and cone that together are necessary and sufficient. Any suggestions, counterexamples or pointers to the literature that anyone may have will be greatly appreciated. UPDATE: Cleaned it up a bit, and posted some new information I found since first posting. I found no mention in any literature to this question. I also asked around a bit with no hits from people who are a bit in the know, so it seems to be wide open. Gets the 'open-problem' tag.

Interesting result on the Euler-Maschroni constant - what is the background?

Today I entered the following expression in maple: $$a_i = H_{10^i} - ln(10^i) - \gamma$$ Here H_j equals $\sum_{k=1}^{j} 1/k$ and γ is the Euler-Mascheroni constant. When I computed a_n for $i = 0$ to 10 I obtained the following results: $i = 0$;
4.22784335098467139393487909917597568957840664060076401194232765115132 3 * 10^{-1} $i=1$;

What is the status of the subadditivity problem for analytic capacity?

Hi, Here is another question that concerns analytic capacity. For a compact set K in the plane, define the analytic capacity of K by $$\gamma(K):=\sup|f'(\infty)|,$$ where the supremum is taken over all functions f holomorphic and bounded by 1 in the complement of K. Here $$f'(∞)=\lim_{z \rightarrow \infty}z(f(z)-f(\infty)).$$ It was conjectured by Vitushkin, in view to applications in approximation theory, that analytic capacity is semi-additive, i.e. there exists a universal constant C such that $$\gamma(E \cup F) \leq C(\gamma(E) + \gamma(F)).$$ This was proved by Tolsa in 2003. From what I know, wether or not analytic capacity is subadditive, i.e. if we can take $C=1$, is still open. However, I can't find much about this problem in the literature, hence the question : What is the status on this problem? Has it been proved that analytic capacity is indeed subadditive in some particular cases? The only thing I found about this is an article by Suita, "On subadditivity of analytic capacity for two continua.", in which it is proved that analytic capacity is subadditive in the case where E,F are disjoint connected compact sets. The proof relies deeply on the fact that for compact connected sets, analytic capacity equals logarithmic capacity, which does not hold in the disconnected case. Any reference about this is welcome. Thank you, Malik

Avoidable words

Let $u(x_1,...,x_n)$ be a word, $k\in \mathbb{N}$. We say that u is k-avoidable if there exists an infinite word in k letters $\{a_1,...,a_k\}$ which does not contain values of u (i.e. words of the form $u(v_1,...,v_n)$, $v_i\in \{a_1,...,a_k\}^+$ as a subword. For example x^3 is 2-avoidable and x^2 is 3-avoidable but not 2-avoidable because two infinite words constructed by Thue and Morse avoid x^2 and x^3. All avoidable words have been described by Bean-Ehrenfeucht-McNulty and Zimin (see these slides of George McNulty's talk, for example. Is there an example of a 6-avoidable but not 5-avoidable word? The word x^3 is 2-avoidable but not 1-avoidable. The word x^2 is 3-avoidable (Thue) but not 2-avoidable (obvious). Walter's word $$abwbcxcayba$$ is 4-avoidable but not 3-avoidable. Ronald Clark in his PhD thesis proved that $$abubawacxbcycdazdcd$$ is 5-avoidable but not 4-avoidable (see Clark, Ronald J. The existence of a pattern which is 5-avoidable but 4-unavoidable. Internat. J. Algebra Comput. 16 (2006), no. 2, 351-367.) It is of course hard to believe that every avoidable word is 5-avoidable (or C-avoidable for any constant C). There were rumors that an example of a 6-avoidable word which is not 5-avoidable has also been constructed. What is the status of that question? Update Since according to James Currie, the above is almost as much as we know, as far as the lower bound is concerned, here is the best upper bounds I know. Let k ibe the number of letters in an avoidable word u, $n=n(k)$ is the minimal n such that all such u are n-avoidable. An exponential upper bound for $n(k)$ was found in the original papers by Bean-Ehrenfeucht-McNulty and Zimin, quadratic upper bound - in my paper, "Problems of Burnside type and the finite basis property in varieties of semigroups". Math. USSR-Izv. 30 (1988), no. 2, 295-314 (I considered a more complicated problem of avoidability of identities) and a linear upper bound $9k+20$ in Baker, McNulty, Taylor, Growth problems for avoidable words. Theoret. Comput. Sci. 69 (1989), no. 3, 319-345. The best upper bound I know is $n(k)\le 3\lfloor k/2\rfloor+3$. It was proved by Irina Mel'nichuk in "On the existence of infinite finitely generated free semigroups in some varieties of semigroups", Leningrad Algebraic Systems with One Operation and Relations (1985), pp. 74-83. George McNulty claims in the talk I linked to above that Mel'nichuk proved the upper bound $k+6$ in 1988, but I could not find a reference. The question is whether $k(n)$ is bounded by a constant.

The shortest path in first passage percolation

Update (January 17): The problem has now been solved by Daniel Ahlberg and Christopher Hoffman. (Thanks to Matt Kahle for informing us.) Consider a square planar grid. (The vertices are pair of points in the plane with integer coordinates and two vertices are adjacent if they agree in one coordinate and differ by one in the other.) Give every edge a length one with probability a half and length two with probability a half. Consider a shortest path between the origin and the vertex $(n,0)$. Show that with probability that tends to one as n tends to infinity the shortest path will not contain the "middle edge" on the x-axis inbetween the orgin and $(n,0)$. (Namely, the edge between the vertices $(\lfloor\frac{n}{2}\rfloor,0)$ and $(\lfloor\frac{n}{2}\rfloor+1,0)$.) This question is in the category of "a missing lemma". It is not really a full fledged open problem but rather a statement which looks correct that was needed in some paper and resisted proof. Of course, some such "lemmas" turn out to be very difficult, but sometimes maybe a simple argument was simply missed. The relevant paper is Itai Benjamini, Gil Kalai, and Oded Schramm, First Passage Percolation Has Sublinear Distance Variance, Ann. Probab. 31(4) (2003) pp 1970-1978, doi:10.1214/aop/1068646373, arXiv:math/0203262. While MO have chosen to accept one answer, and there were some nice suggestions, the problem is still wide open.

Open problems/questions in representation theory and around?

What are open problems in representation theory? What are the sources (books/papers/sites) discussing this? Any kinds of problems/questions are welcome - big/small, vague/concrete. Some estimation of difficulty and importance, as well as, small description, prerequisites and relevant references, ... are welcome. To the best of my knowledge, there are NO good lists of representation theory problems on the web. E.g. the sites below contain lots of unsolved problem in other areas, but not in representation theory: http://en.wikipedia.org/wiki/Unsolved_problems_in_mathematics http://garden.irmacs.sfu.ca/ http://maven.smith.edu/~orourke/TOPP/ MO questions also discuss other fields, but not representation theory: What are the big problems in probability theory? What are some open problems in algebraic geometry? What are some open problems in toric varieties? More open problems Open problems with monetary rewards Open problems in Euclidean geometry? Open Questions in Riemannian Geometry What are some of the big open problems in 3-manifold theory? Open problems in continued fractions theory

Entropy of Bernoulli walks on semi-groups.

Consider the Fibonacci semi-group $<L,R|LRR=RLL>$ with a Bernoulli walk $P(R)=p, P(L)=1-p$. Is the entropy $H(p)$ an unimodal function with maximum at p=0.5? Is this true for all finitely generated semi-groups (with some symmetries)? For the free semi-group $<L,R>$ (the Shift space) it is well known and easy to prove that $H(p)=-(plog(p)+(1-p)log(1-p))$.

vector balancing problem

I believe the solution posted to the arXiv on June 17 by Marcus, Spielman, and Srivastava is correct. This problem may be hard, so I don't expect an off-the-cuff solution. But can anyone suggest possible proof strategies? I have vectors $v_1, \ldots, v_k$ in ${\bf R}^n$. Each of them has euclidean length at most $.01$, and for every unit vector $u \in {\bf R}^n$ they satisfy $$\sum_{i=1}^k |\langle u,v_i\rangle|^2 = 1.$$ Is it possible to find a set of indices $S \subset \{1, \ldots, k\}$ such that $$.0001 < \sum_{i \in S} |\langle u,v_i\rangle|^2 < .9999$$ for every unit vector u? This will imply the same bounds when summing over the complement of S. The $.01$ and $.0001$ aren't important; I just need the result for some positive δ and ϵ. But they have to be independent of k and n. (This may seem unlikely, until you try to construct a counterexample.) The motivation is that this is a (very slightly simplified) equivalent version of the famous Kadison-Singer problem. A solution would have important consequences in operator theory, harmonic analysis, and C*-algebra. Many people have worked on this problem, but perhaps not in the above form, which I feel exposes the combinatorial difficulty which is the real root of the problem.

Does smooth and proper over $\mathbb Z$ imply rational?

Does smooth and proper over $\mathbb Z$ imply rational? I think someone told me that this is a standard conjecture. Is it a widely held? held at all? Did someone in particular make this conjecture? write it down somewhere? give evidence for it? Would you like to provide evidence? Why rational and not, say, unirational? Fontaine's non-digitized letter to Messing shows that if X is smooth and proper over $\mathbb Z$, then the low degree nondiagonal Dolbeault groups vanish $H^q(X_{\mathbb Q}; \Omega^p)=0$ for $p\ne q$, $p+q\leqslant 3$. An obvious conjecture is to remove the degree restriction. Is this expected? Does this conjecture imply the rationality one? (This hypothesis on a single space does not force rationality: there are fake projective planes that mimic the cohomology of the real projective plane, but they have finite covers that would again be smooth and proper, but which can't have such cohomology by the Atiyah-Bott fixed point formula. a little more here) What I'm looking for: A citation of a survey would be ideal. Short of that, I would accept a citation of someone making this conjecture (which may well be the paper I cite above). In any event, I would be happy if people provide evidence for or against the conjecture. Some definitions: propriety is a relative version of compactness; let's just say that the scheme is cut out of projective space by homogeneous equations with coefficients in $\mathbb Z$. Smoothness means that the fibers, that is, the schemes defined by the same equations considered over finite fields (or their algebraic closures) are smooth. This is stronger than regularity of the total space and more like a submersion, so by analogy with Ehresmann's theorem, all the fibers are supposed to be "the same." For example, $\operatorname{Spec}\mathbb Z[i]$ is regular, but the map to $\operatorname{Spec}\mathbb Z$ is not smooth, but ramifies at (2). (Geometrically) rational means that that the field of rational functions with complex coefficients are the same as on $\mathbb CP^n$, namely $\mathbb C(x_1,\ldots,x_n)$. I think this question shows that strict rationality, a fraction field of $\mathbb Q(x_1,\ldots,x_n)$, is too much to ask for. To complete the list of relevant MO questions, would (geometric) rationality imply a Hasse principle, answering this question?

Local structure of rational varieties

I've been asked this question by a colleague who's not an algebraic geometer; we both feel that the answer should be "no", but I don't have a clue how to prove it. Here's the question: let X be a smooth rational variety (over the complex numbers, say). Is it true that every point of X has a Zariski open neighbourhood that is isomorphic to an open subset of ${\mathbb P}^n$?

distance regular metric spaces

A metric space (V,d) will be called distance regular if for every distances a>0, b, c a nonnegative integer p(a,b,c) is defined, so that whenever d(B,C)=a, there are precisely p(a,b,c) points A such that d(A,B)=c, d(A,C)=b. The Euclidean plane is an example: p(a,b,c)=0,1, or 2 when the triangle inequality for a,b,c, correspondingly, fails, turns into equality, or is strict. If we also require that p(a,b,c)>0 whenever the triangle inequality does not fail, then I conjecture that this is the only possibility for the parameters p(a,b,c). That is, there may be many non-isomorphic examples, but the parameters will be the same for all of them. (Thanks to Heather for this clarification.) Has anybody formulated/proved/refuted this conjecture before? It looks very natural. UPD. I should have mentioned this: "for every distances a>0, b, c" means all nonnegative reals, and the same for "whenever the triangle inequality does not fail". In particular this means that all positive real distances actually occur. UPD2. After a week trial, the question seems to be new, open, and interesting. Anton suugested a line of attack, and I believe I can write down the proof of the first step: that p(a,b,c)=1 when the triangle inequality turns into equality. Fedja produced examples showing that this first step is indeed essential. I'm adding the "open problem" tag to the question.

Inequality with Euler's totient function

In A conjecture concerning primes and algebra on MSE, I defined a multiplicative function $\omega:\mathbb Z_+\!\!\to\mathbb Z_+$ with $\omega(p_n)=n$, for the n-th prime p_n. It was conjectured that $\omega(N)\leq\pi(N)$ for $N>49$, where π is the prime-counting function (which seems to be solved by a nice lemma by Greg Martin). Now I have found another conjecture concerning ω. I have tested $\varphi(N)\geq\omega(N)$ for all $N<1.000.000$, where φ is the Euler totient function, without finding a counterexample. The conjecture, for which I would like a proof or a counter proof, is then: $\displaystyle n\prod_{p|n}\left(1-\frac{1}{p}\right)\geq\prod_{k\geq 1}k^{n_k}$, where $\displaystyle n=\prod_{k\geq 1}p_k^{n_k}$. Notes: φ is multiplicative, $\varphi(mn)=\varphi(m)\varphi(n)$, for $(m,n)=1$ ω is completely multiplicative, $\omega(mn)=\omega(m)\omega(n)$ for all $m,n\in\mathbb Z_+$. The inequality $\varphi(N)\geq\pi(N)$ should also be true, for sufficiently large N, but I haven't found anything about this on internet. Jaycob Colemans comment seems to prove the inequality: $\displaystyle \prod_{p_k,n_k\ne0}\left(1-\frac{1}{p_k}\right)\geq\prod_{p_k,n_k\ne0}\frac{k^{n_k}}{p_k^{n_k}}$, since $\displaystyle \frac{p_k-1}{p_k}\geq\left(\frac{k}{p_k}\right)^{n_k}$.

Conjecture on the value of limit and related primality testing

Just I made a curious conjecture when I was playing with my calculator. We will use $\displaystyle\prod_{i=1}^n p_i$ where p_i is the i-th prime. Then I have noted that, $$\left\lvert\cos \left(\displaystyle\prod_{i=1}^3 p_i\right)\right\rvert=\left\lvert\cos \left(\displaystyle\prod_{i=1}^4 p_i\right)\right\rvert=\left\lvert\cos \left(\displaystyle\prod_{i=1}^5 p_i\right)\right\rvert=\dfrac{\sqrt{3}}{2}$$ The typical thing is that if in case of the product of consecutive primes we take any composite number then the equality doesn't hold. For example $\left\lvert\cos (2\cdot 3 \cdot 5 \cdot 6)\right\rvert \neq \dfrac{\sqrt{3}}{2}$, $\left\lvert\cos (2\cdot 3 \cdot 5 \cdot 7 \cdot 8)\right\rvert \neq \dfrac{\sqrt{3}}{2}$. Now since I am calculating on a 12-digit calculator, I don't have plenty of evidence. Basing upon this very little evidence I am putting forward a conjecture. Conjecture $$\displaystyle\lim_{n\to \infty}\left\lvert\cos \left(\displaystyle\prod_{i=1}^n p_i\right)\right\rvert=\dfrac{\sqrt{3}}{2}$$ I think that both the conjectures are probably false but I can't prove or disprove anyone of them. Though counterexamples are welcome but in that case I will be glad to know if there are infinitely many counterexamples or not.

Conjecture: three or more decompositions into powers with a base differing by 1 means its a perfect power

If $$(i_1)^{a_1}(i_1+1)^{b_1}=n $$ $$(i_2)^{a_2}(i_2+1)^{b_2}=n $$ $$(i_3)^{a_3}(i_3+1)^{b_3}=n $$ where all the terms are positive integers and the groups $(i_1,a_1,b_1),(i_2,a_2,b_2),(i_3,a_3,b_3)$ are different (i.e. n is being decomposed in 3 different ways) then n is a perfect power, i.e. it is expressible in the form $j^c = n$, where $c>1$. I have tested this up to 10^{14} and not found a counterexample. Furthermore, I have never found an integer which can be expressed like this in four ways, i.e. with the addition of $(i_4)^{a_4}(i_4+1)^{b_4}=n$. Is it generally true, and if so can it be proved? Examples $$576=2^{6}.3^{2}=3^{2}.4^{3}=8^{2}.9^{1}$$
$$5184=2^{6}.3^{4}=3^{4}.4^{3}=8^{2}.9^{2}$$

Conjecture about the powers of 2 in the prime factorizations of the series $a_n = n(n+1)(n+2)$

I found the following law and would like to know what do you think about it and if anyone can explain why this is so. Also, is this already known and proven? Consider the following series: $$1\times2\times3, 2\times3\times4, 3\times4\times5,\ldots,n(n+1)(n+2)$$ or more compactly: $$a_n = n(n+1)(n+2)$$ Lets take the prime factorization for every element of a_n: $$2\times3, 2^3\times3, 2^2\times3\times5,2^3\times3\times5,\ldots$$ Lets take all the powers of 2 in every prime factorization in the above series and create a sequence out of them, and then group the elements of that sequence in tuples with size 4. The result of this we will call p_1. $$p_1 = (1,3,2,3),(1,4,3,4),(1,3,2,3),(1,5,4,5),\ldots$$ It seems that every 4-tuple with odd index in p_1 is $(1,3,2,3)$. Lets remove all 4-tuples with odd positions from p_1 and call the result p_2: $$p_2 = (1,4,3,4),(1,5,4,5),(1,4,3,4),(1,6,5,6),\ldots$$ Now p_2 will have $(1,4,3,4)$ at every odd position. If we take the p_3 sequence to have only those elements of p_2 that are with even indices, p_3 will have $(1,5,4,5)$ at every odd position. And so on... p_n will have $(1, n+2, n+1,n+2)$ at every odd position.

Two conjectures regarding $\varphi(n)$

There is a famous unsolved problem called Lehmer's Totient Problem which states that, $\varphi(n)\mid n-1 \implies n$ is a prime. Where $\varphi(n)$ is Euler's Totient Function. I was wondering about two conjectures of my own which I found unable to prove or disprove myself. The conjectures are, Conjecture 1 If n is an odd integer then $\varphi(n)+1\mid n \implies n$ is a prime. Conjecture 2 For odd n, $\varphi(n)+1\mid n\iff \varphi(n)\mid n-1$ Note that both the conjectures are independent of one another and the proof of any one willn't shed light on the proof of disproof the other unless a proof or disproof of Lehmer's original conjecture is done. So, can anyone help me in proving anyone of the conjectures? Note:- I don't know whether my conjectures are already well-known conjectures or not. If that's the case then any reference to the authentic source(s) will be enough. Added:- The conjectures are now edited taking in view the suggestions of fretty and A. Nicolas.

Problems about consecutive semiprimes

I was playing around with semi-prime numbers and I made two conjectures, which are: Given any integer a, at least one of $a,(a+1),(a+2)$ or $(a+3)$ is not semi-prime. There are infinitely many integers a, such that $a,(a+1)$ and $(a+2)$ are semi-primes. I've written a computer program to verify the conjectures for values up to 700,000 (so, there's a high chance that they are both true). Can anyone give a proof or counter example for any of these problems, or a link to a paper on the subject? Thanks!

Prove or disprove this upper bound on chromatic number.

Let G be a simple connected finite graph and let $v \ge 4$ be the number of vertices, E the number of edges, $\chi(G)$ the chromatic number , $\omega(G)$ the clique number and Δ the maximum degree of G. Let $C(G)$ be a function of G which is equal to 3 when G contains cycles of odd length. Let $ {(d_1,d_2,...)}$ be the degree sequence of G. Let $i > 4$ be the smallest integer such that $$ \left\lceil \frac{(0.5\sum\limits_{j=1}^i d_j) -i}{i-3} \right\rceil < \frac{i}{2}$$ and $$ 2\frac{(0.5\sum\limits_{j=1}^i d_j) -i}{i-3} < \Delta $$ Take $i = v$ if a minimum value does not exist. Let $ B = 4 $ if $$ ^{**}1.5\leq\frac{(0.5\sum\limits_{j=1}^i d_j) -i}{i-3} < 2 $$ Otherwise $$ B = \left\lfloor 2\frac{(0.5\sum\limits_{j=1}^i d_j) -i}{i-3} \right\rfloor $$ Then $$\chi(G) \le \max\left\{C(G)\ , B,\ \omega(G)\right\}$$ ========== I've edited it completely because of bof's answer. ** I'm not too sure if this lower bound should be 1 or 1.5.

Explanation for relationship between hypotenuse segments and leg lengths?

|` | ` x | ` | ` c a | z /` | / ` y |_/ ` |/|_____` b I'm new to this SE, but I have an SO account, so hello! Assume that z is the altitude that intersects the hypotenuse, and x and y are the resulting line segments. This is what my friend had to say about this. $$ z = \sqrt{xy} $$ You cannot find z with a and b. Here's what I said. Somehow, a and b must be related to x and y. At first I thought that $$\frac{a}{a+b} * c = x$$ That was wrong, as the altitude did not bisect the right angle. Through some thinking, but not proving, I said this, which was correct, AFAIK. $$\frac{a^2}{a^2+b^2} * c = x\\\\\frac{b^2}{a^2+b^2} * c = y $$ Some simplifying ensued. $$\frac{a^2}{c^2} * c = x\\\\\frac{b^2}{c^2} * c = y $$ More. $$\frac{a^2}{c} = x\\\\\frac{b^2}{c} = y $$ Now that a and b were used to find x and y, I got z with the geometric mean. $$ z = \sqrt{\frac{a^2}{c} * \frac{b^2}{c}} $$ That goes to: $$ z = \frac{ab}{c} $$ This was all and well, but then I was asked how did you come up with the first step?

Does any sum of twin primes, where the sum is greater than 12, also represents the sum of 2 other distinct primes?

I was in the midst of proving a conjecture when I came across an observation that led me to forming a potentially new conjecture. The conjecture goes as follows: Any given sum of twin primes (specifically the two primes in a twin prime pair, ie. 11 and 13) where the sum is greater than 12, also represents the sum of 2 other distinct primes. I've proven this for the first 1000 twin primes and my computer is calculating beyond that set. Anyways, does anybody have any ideas of how I could go about proving this conjecture? I apologize if this conjecture has already been posed.

Generalizing conjecture of Bertrand

Joseph Bertrand's conjecture for primes from 1845, $\;p_{n+1} < 2p_n$, proved by Chebyshev 1852, can be generalized as follows: $$\forall a\in\Bbb Z_+\exists N\in\Bbb Z_+:(n\ge N\implies\exists p\in\Bbb P: ap_n<p<(a+1)p_n)$$ It seems to be proved for $a=2,3$ that $N=1$ works (Wikipedia). Computer tests for $p_n< 10,000,000$ $(n\le 664,579)$: $a=5,9,14$ holds for all primes $p_n\ge 2$, that is, it seems to hold for $N=1$. The case $a=4$ is tested for $p_n\ge 5\; (N=3)$. The case $a=25$ is tested for $p_n\ge 23\; (N=9)$. Computer tests for $p_n<1,000,000\;(n\le 78,498)$: Computer tests for $p_n<100,000\;(n\le 9,592)$: What is known about this? Is the conjecture possible to prove?

In the Collatz function, why does 2^k-1 reach 3^k-1 after $2k$ steps, and could it be used to find divergent trajectories?

If you start calculating the Collatz function from an integer of the form 2^k-1, you will reach 3^k-1 after $2k$ steps. So, it is possible to pick a starting value that continuously zig-zags upwards for a period of time that can be easily defined. Has this property been used in trying to find divergent trajectories? One could say something like that when the starting value grows exponentially, the longest possible continuously growing sub-sequence expands linearly. Well.. you get the point

Power towers of 2 and 3 - looking for a proof

Let $\uparrow$ denote the right-associative exponentiation operator: $a\uparrow b\uparrow c=a\uparrow(b\uparrow c)=a^{b^c}$ There is a sequence $A248907$ recently submitted to OEIS (see also $A256179$): $2, 3, 22, 23, 32, 222, 33, 322, 223, 232, 323, 332, 2222, 3222, 233, 333, 2322, ...$ It represents all power towers of numbers 2 and 3 in increasing order. In other words, it consists of all non-empty finite strings over the alphabet $\{2,3\}$ ordered in such a way, that once each string of digits is interspersed with the $\uparrow$ operators and evaluated, the sequence of results is monotonically increasing, i.e. $2=2$ $3=3$ $2\uparrow2=4$ $2\uparrow3=8$ $3\uparrow2=9$ $2\uparrow2\uparrow2=16$

$3\uparrow3=27$ $3\uparrow2\uparrow2=81$ $...$ I'm interested in a reasonably efficient algorithm for generating n^th element of $A248907$ (denote it a_n). It should avoid direct evaluation of power towers, otherwise it would easily run into huge numbers that would make the algorithm unfeasible in practice. I have a recursive algorithm that I suppose does the right thing, but I lack a rigorous proof of that. If $n\le12$, the corresponding elements $a_1\,..\,a_{12}$ are $2, 3, 22, 23, 32, 222, 33, 322, 223, 232, 323, 332;$ Otherwise, if n is odd, a_n is $a_{(n-1)/2}$ with the digit 2 prepended to it; Otherwise (n is even), a_n is $a_{(n-2)/2}$ with the digit 3 prepended to it. This algorithm builds the sequence from an "irregular" initial segment, and a "regular" tail consisting of pairs of elements that differ by the first digit (2 or 3, interleaved) that is prepended to previous elements taken sequentially from a certain offset, each element is used twice. Could you please help me prove (or disprove) its correctness?

Asymptotic behavior of the zeros of the digamma function

The gamma function has just one extremum on each interval $(k,k+1)$, where k is a negative integer. These extrema occur at the zeros of the derivative of the gamma function. Let z_n denote the n-th greatest zero, or the zero found on the interval $(-n, -n+1)$. As n grows, z_n nears $-n$. In other words, $z_n+n=\{z_n\}=z_n-\lfloor z_n\rfloor$ nears 0. I have numerically found $\{z_n\}^{-1}$ to be asymptotically equivalent to $\log(n)$: Here's the kicker, though. It seems that $\lim\limits_{n\to\infty}\left(\{z_n\}^{-1}-\log(n)\right)\approx 1-\gamma$. I appear to be reaching the limits of double precision. At $n=1754$, I start getting (presumably) wildly inaccurate values for z_n. If my approximations can be trusted before this point, however, then $\{z_n\}^{-1}-\log(n)+\gamma$ decreases and reaches about 1 at $n=1713$, but continues decreasing below 1. If this is truly the case, then the claim in the previous paragraph is not a strict equality. Does anyone know of a proof of $\{z_n\}^{-1}\sim\log(n)$ or if $\lim\limits_{n\to\infty}\left(\{z_n\}^{-1}-\log(n)\right)= 1-\gamma$ is true? I welcome any analytical or numerical evidence hinting at the confirmation or negation of either of these two statements. I myself know next to nothing about the gamma function or its relatives, but I noticed the zeros drifting left on their intervals and decided to investigate.

Can I demonstrate a proposition without a rigorous proof?

Writing a paper, I want to declare a certain proposition, but is only supported by other research's empirical result. In this sort of case, what can I name to my argument in my paper? CONJECTURE is so much informal and seems to be so lazy. Otherwise, is it possible just to write down PROPOSITION in my paper without rigorous proof, but with some procedures attaining to that proposition including previous empirical results? Thank in advance!

Conjectured diagonal Ramsey numbers

While doing some reading on the Wikipedia page for Ramsey numbers, I stumbled upon OEIS sequence A120414, which lists the allegedly conjectured values of the diagonal Ramsey numbers $R(n,n)$. I haven't found any indications in the standard web resources (WP, Mathworld) that suggest that any of the numbers in the known ranges for $R(n,n)$, $n\geq 5$ is more probable than others. What is this conjectured list based on? Considering the age of references on the OEIS page, the answer is probably elsewhere.

Euler's Totient function $\forall n\ge3$, if $(\frac{\varphi(n)}{2}+1)\ \mid\ n\ $ then $\frac{\varphi(n)}{2}+1$ is prime

While I was studying Euler's Totient function, $\varphi(n)$, I stumbled upon the marvelous book "Index to Mathematical Problems, 1980-1984" By Stanley Rabinowitz. In this page of the book (link to Google books sample), the open problems and conjectures about the Totient function appear. All are really awesome, but one of them was specially interesting to me: CMB34 by M.V.Subbarao: if $(\varphi(n)+1)\ \mid\ n$ then, n or $n/2 \in \Bbb P$. Well it has two parts, the 'trivial' one is that if n is indeed a prime number, $\varphi(n)=n-1$, so $\varphi(n)+1 = n-1+1 = n$, and then $n \mid n$. But the other part is not trivial: when $(\varphi(n)+1)$ divides n (even), then $n/2$ is a prime number. Simply amazing and still open (if I am not wrong). I wanted to learn more, so I did my own try-outs of other combinations like CMB34, and I did find one that is very interesting, indeed I did not find any open conjecture or open problem about it, so here is my own proposed statement: (1) $\forall n\ge3$, if $(\frac{\varphi(n)}{2}+1)\ \mid\ n\ $ then $(\frac{\varphi(n)}{2}+1)\in \Bbb P$ And it really seems to work! I have made a Python test in the interval $[1,50000]$ and the statement is always true, no counterexamples. Here are some samples: $n = 52,\ \varphi(n)=24,\ \frac{\varphi(n)}{2}+1=13,\ 13\mid52$, and $13 \in \Bbb P$ $n = 57,\ \varphi(n)=36,\ \frac{\varphi(n)}{2}+1=19,\ 19\mid57$, and $19 \in \Bbb P$ $n = 66,\ \varphi(n)=20,\ \frac{\varphi(n)}{2}+1=11,\ 11\mid66$, and $11 \in \Bbb P$ $n = 68,\ \varphi(n)=32,\ \frac{\varphi(n)}{2}+1=17,\ 17\mid68$, and $17 \in \Bbb P$ $etc.$ Having those results in mind, I tried to generalize to $\frac{\varphi(n)}{2^i}+1, i\in\Bbb N$. And for instance for the case $i=2, (2^2)$, apart from some specific initial small n counterexamples $n = \{3,4,6,28,36,66\}$, for $n\gt66$ seems to be always true as well. I still did not try other values of i. I have uploaded the test written in Python here. I have continued trying to generalize, and the following statement seems also to be true always: (2) $\forall n\ge3, n=2k,\ k\in \Bbb N$, if $(\frac{\varphi(n)}{2}+1)\ \mid\ \frac{n}{2}\ $ then $(\frac{\varphi(n)}{2}+1)\in \Bbb P$ There are two differences with my main statement (1): in this case, n can only be an even number ≥3, so it can be divided by 2, and the relationship is true when a factor of $n/2$ is found (instead of a factor of n). I will update

the question if I find more successful combinations. The same can be applied to those n multiples of 4, and in this case, the expression is (trivially) true when $n = 4p\ \forall p \in \Bbb P, p\ge3$, so the list of odd primes appears in the original natural order of the prime numbers: (3) $\forall n\ge3, n=4k,\ k\in \Bbb N$, if $(\frac{\varphi(n)}{2}+1)\ \mid\ \frac{n}{4}\ $ then $(\frac{\varphi(n)}{2}+1)\in \Bbb P$ This is in other words: (3) $\forall n\ge3, n=4k,\ k\in \Bbb N$, if $\frac{n}{4} = (\frac{\varphi(n)}{2}+1)$ then $(\frac{\varphi(n)}{2}+1)\in \Bbb P$ In this case, the relationship is trivial for those $n=4p$ multiples of any p prime, because $\frac{\varphi(4p)}{2}+1 = \frac{\varphi(4)*\varphi(p)}{2}+1 = \frac{2*\varphi(p)}{2}+1 = \varphi(p)+1 = p-1+1 = p$ But the interesting point is that if n is a multiple of $4\ /\ n\not=4p, p \in \Bbb P$ then the relationship is false always, so no primes are found. Anyway, the expressions (1) and (2) seem more interesting than (3). I did not find any n able to make the relationship true for $\frac{n}{8}$ or $\frac{n}{16}$. The prime numbers $p = (\frac{\varphi(n)}{2}+1)$ generated by the expression (1): Except for the case $n=6$ in the rest of cases the prime number p seems to be always the greatest prime factor of n. Trivial but interesting, if p is factor of n, then (n/p) is an upper bound of the other prime factors of q, so $\forall q, q\in \Bbb P\ /\ q \not= p, \ q\mid n, \ q\le(n/p)$. And n is a subset of the numbers following the pattern: $n=(\frac{\varphi(n)}{2}+1)*k_1 /\ k_1 \in \{2,3,4,6\}$ It could be possible that I can not see the wood for the trees, and my statement is trivial, or already known, or nonsense, so I would appreciate any help to understand those results. I would like to share with you the following questions: Is my proposed statement about the Totient function already known or trivial? Is there a counterexample of it? Could it be generalized? Thank you! ** UPDATE 2015/04/22 ** My definition about the numbers n covering the properties explained at the statement (1) has been accepted at OEIS! (link here). ** UPDATE 2015/05/01 ** Related question about other possible interesting property (link here): (2)$\ \forall n\in [3,29]\cup[31,1000000]$, if $[(\frac{\varphi(n)}{2}+1)\ \mid\ n]\ \land\ [(\frac{\tau(n)}{2}+1)\ \mid\ n]\ $ then $[(\frac{\varphi(n)}{2}+1)\cdot(\frac{\tau(n)}{2}+1)] = n$

Euler's Totient function $\forall n\ge3$, if $(n-\phi(n)) = \sqrt{n}\ $,$\ $then $(n-\phi(n)) \in \Bbb P$

Recently I opened a question about what it might be a new property of Euler's Totient function. I am still studying the Totient function and I found another interesting relationship, it is very different from the ones I wrote in my former question, so I would like to ask about it apart because this might be another interesting topic. As far as I have checked, I did not find any reference to this property, but if I am wrong I will remove the question. This is my new proposed statement: $\forall n\ge3$, if $(n-\phi(n)) = \sqrt{n}\ $,$\ $then $(n-\phi(n)) \in \Bbb P$ Meaning that $n=p^2$ is the perfect square of a prime p if and only if the distance between n and $\phi(n)$ is exactly p. I have also tested this using Python, and no counterexamples are found in the interval $[1..7000]$. Usually when I find these kind of possible properties I test them, but I do not have enough theoretical knowledge to prove them, so any comment, hint or explanation about it is very appreciated. So as usual my questions are: Is my proposed statement about the Totient function already known or trivial? Is there a counterexample of it? Thank you!

Prove that $\det(A) \cdot v \, A^{-1} = \det(A+uv) \cdot v \, (A+uv)^{-1}$.

Let A be a $n \times n$ matrix, u a $n \times 1$ matrix and v a $1 \times n$ matrix. If A and $(A+uv)$ are invertible, prove that $$ \det(A) \cdot v \, A^{-1} = \det(A+uv) \cdot v \, (A+uv)^{-1}. $$ I have numerical evidence that this is true, but I cannot prove it. Note that the term on the left does not depend on u! Thank you.

Euler's totient and divisors count function relationship when $[(\frac{\varphi(n)}{2}+1)\cdot(\frac{\tau(n)}{2}+1)] = n$

I am studying the Euler's totient function $\varphi(n)$ and the divisors count function, $\tau(n)$, also named $d(n)$, and recently opened a question (link here) about the following condition: (1)$\ \forall n\ge3$, if $(\frac{\varphi(n)}{2}+1)\ \mid\ n\ $ then $(\frac{\varphi(n)}{2}+1)\in \Bbb P$ I wanted to do the same exercise, but adding an extra restriction regarding the divisors count function, $\tau(n)$, and I found the following to be true in the interval $[3,29]\cup[31,10^9]$ except for only one isolated counterexample at $n=30$: (2)$\ \forall n\in [3,29]\cup[31,10^9]$, if $[(\frac{\varphi(n)}{2}+1)\ \mid\ n]\ \land\ [(\frac{\tau(n)}{2}+1)\ \mid\ n]\ $ then $[(\frac{\varphi(n)}{2}+1)\cdot(\frac{\tau(n)}{2}+1)] = n$ So basically when the condition (1) happens and also the restriction $(\frac{\tau(n)}{2}+1)\mid n$ happens, then both $(\frac{\varphi(n)}{2}+1)$ and $(\frac{\tau(n)}{2}+1)$ are factors of n and if they are multiplied they are exactly n. E.g.: $n=21\ ,\ (\frac{\varphi(21)}{2}+1)=7 = a\ ,\ (\frac{\tau(21)}{2})+1=3 = b\ ,$ and $a\cdot b = 7\cdot3 = 21$ $n=999993\ ,\ (\frac{\varphi(999993)}{2}+1)=333331 = a\ ,\ (\frac{\tau(999993)}{2})+1=3 = b\ ,$ and $a\cdot b = 333331\cdot3 = 999993$ The only counterexample I found so far is: $n=30\ ,\ (\frac{\varphi(30)}{2}+1)=5 = a\ ,\ (\frac{\tau(30)}{2})+1=5 = b\ ,$ and $a\cdot b = 5\cdot 5 = 25 \not= 30$ I have been reading about the properties of both the totient and the divisor count functions, but I do not understand why always seems to happen (2), except for $n=30$, so I wanted to share with you these questions: Is it trivial? can be obtained by knowing the properties of $\varphi(n)$ and $\tau(n)$? Is there another counterexample for $n\gt10^9$? If somebody could check further would be very appreciated. Any hint or explanation about why (2) happens is very welcomed, thank you! UPDATE 2015/05/25 Tested up to 10^9, no counterxamples found apart from $n=30$. Here is the PARI/GP code: eulerdiv(limitval)={ for (n = 1, limitval, mytot = (eulerphi(n)/2)+1; mydiv = (numdiv(n)/2)+1; if ((n%mytot==0) && (n%mydiv==0), if((mytot*mydiv)==n,,print("Counterexample: "," ",n," ",mytot," ",mydiv)))) }

Does $|n^2 \cos n|$ diverge to $+\infty$?

I was recently exposed to the problem of deciding whether $$ \lim_{n \to +\infty} |n \cos n| = +\infty$$ where the limit is taken over the integers. As $|\cos n|$ oscillates throughout the interval $[0,1]$, it seems plausible that every real number ought to be a limit point of this sequence. But to show the limit doesn't exist, it's enough to show the sequence is less than 2 infinitely often, and this can be done with continued fractions: we can find arbitrarily large p and q with q odd such that $$ \left| \frac{\pi}{2} - \frac{p}{q} \right| < \frac{1}{q^2} $$ which implies $$ \left| \frac{q-1}{2} \pi + \frac{\pi}{2} - p \right| < \frac{1}{q} $$ making p a good approximation of $\pi/2$ modulo π, and thus $$ \left| p \cos p \right| < \frac{p}{q} < 2 $$ This method fails if we consider instead the sequence $n^{1+\epsilon} \cos n$, since the final inequality is an increasing function of n. In fact, a heuristic statistical argument suggests that $$ \lim_{n \to +\infty} |n^{1 + \epsilon} \cos n| = +\infty $$ really does hold: imagine the n's are actually uniformly randomly selected from $[0, \pi]$, there is a roughly $2p/\pi$ chance that $|\cos n| < p$. For any positive constant B, the expected number of terms of $n^{1 + \epsilon} |\cos n|$ which are less than B is $$ \sum_{n=1}^{+\infty} \frac{2B}{\pi n^{1 + \epsilon}} $$ which, in particular, is finite. Of course, this is just heuristic. Does anyone know of a proof or disproof of the conjecture $$ \lim_{n \to +\infty} |n^{1 + \epsilon} \cos n| = +\infty $$ for positive real numbers ϵ, where the limit is taken only over integers? EDIT: Since there have been a few erroneous answers, I'll point out that observing $|\cos n|$ oscillates from 0 to 1 is not enough to show the limit does not exist. Consider the sequence $g(n)$ defined by $g(0) = 1$ $g(n) = \max\{ g(n-1), n / |\cos n| \} + 1$ Then $g(n)$ is an unbounded increasing sequence such that $|g(n) \cos n| > n$ for all n, and thus $$ \lim_{n \to +\infty} |g(n) \cos n| = +\infty $$ Roughly speaking, $g(n)$ diverges to $+\infty$ faster than $n \pmod \pi$ can approximate $\pi / 2$. The question of this post is whether n^2 (or $n^{1 + \epsilon}$) also diverges to $+\infty$ fast enough.

Why is it that if you square two prime numbers and add them, you get a number that is even and is not a perfect square?

If you do $x^2 + y^2 = n$ where x and y are both prime numbers and are both greater than 3, why is n always an even number that isn't a perfect square?

Conjecture about the product of the primitive roots modulo a prime number ($\prod Pr_p$)

While I was learning about the primitive roots modulo $p \in \Bbb P$ (I will call Pr_p to the complete list of the primitive roots module p) and having in mind the conjecture explained in this nice question about the Fortunate numbers and variations of that conjecture for factorials, I found (only empirically tested with Python) that the following expressions are true $\forall p \in [1,1000]$, $p \in \Bbb P$: Let $\mathcal{P}(n)$ be the previous prime smaller than n: $\prod Pr_p\:-\mathcal{P}(\prod Pr_p) = d_1$ is either 1 or a prime. Let $\mathcal{N}(n)$ be the next prime greater than n: $\mathcal{N}(\prod Pr_p)-\prod Pr_p\:= d_2$ is either 1 or a prime. So it seems that the product of the primitive roots modulo a prime p is at a distance d_1 of its previous closer prime and a distance d_2 of its closer next prime, being d_1 and d_2 = 1 or a prime number. E.g.: $Pr_{17}=\{3, 5, 6, 7, 10, 11, 12, 14\}$ $\prod Pr_{17}=11642400$ $\mathcal{P}(\prod Pr_{17})=11642387$, so $d_1=11642400-11642387=13$ $\mathcal{N}(\prod Pr_{17})=11642419$, so $d_2=11642419-11642400=19$ (*) Notice that in the sample by chance d_1 and d_2 incidentally are exactly the previous and next prime numbers of the original $p=17$. I just like to play with the numbers and find relationships between them that I did not know, and usually that is empirical. My theoretical knowledge is quite basic (usually I learn from the answers at MSE very much!). I wanted to share with you the following questions to know more about the properties of the primitive roots modulo p: Does it make sense that according to the definition or properties of the primitive roots modulo a prime p, the product of them was able to have those properties? Is there a counterexample of them? (my computer takes time for bigger values of p so if somebody with Mathematica or other software, a good computer and interested in the topic could give it a try, that would be really appreciated) Is it a trivial property? UPDATE 2015/05/18: added in my blog the Python code for the test in the interval [1,1000]. Thank you!

Conjecture: only one even Fibonacci term divided by two gives a prime: $F(9) = 34 = 2 \times 17$

Every Fibonacci term $F(3n)$ is divisible by two $F(3) = 2$ $F(6) = 8$ $F(9) = 34$ $...$ After seeking Fibonacci tables factorization until $F(10000)$, for every term $\frac{F(3n)}{2}$, it appears there is just one result which is prime $\frac{F(9)}{2} = \frac{34}{2} = 17$ all other $\frac{F(3n)}{2}$ = composite numbers I can't see some reason for this to happen, but since there is no more primes in so huge quantity of terms, I suppose there is not more any prime for $\frac{F(3n)}{2}$ http://mersennus.net/fibonacci Miguel Velilla

Prove that $\lim_{n\rightarrow \infty} \frac{\log_{10}\lfloor\text{Denominator of } H_{10^n}\rfloor+1 }{10^n}=\log_{10} e$

In short, my question is asking to prove that the $$\lim_{n\to\infty}\frac{\text{number of digits in the denominator of} \sum_{k=1}^{10^n} \frac 1k}{10^n}=\log_{10} e$$ I know that the number of digits in a number is $\lfloor \log_{10} n\rfloor +1$ and that the Harmonic numbers are given by $\gamma+\psi_0 (n+1)$, where $\psi_0 (x)=\frac{\Gamma'(x)}{\Gamma(x)}$ but I don't see how to find the number of digits in the denominator of $\psi_0(n+1)+\gamma$. Context:From Wolfram MathWorld, "The numbers of digits in the denominator of H_{10^n} for $n=0, 1, \ldots$ is given by $1, 4, 40, 433, 4345, 43450, 434110, 4342302, 43428678, \ldots$ (OEIS A114468). These digits converge to what appears to be the decimal digits of $\log_{10}e=0.43429448\ldots$ (OEIS A002285)."

A question and a conjecture on $USp(N)$ group

$USp(N)$ with N an even integer is defined as the group of unitary matrices M that satisfy $M^TJM=J$, where M^T is the transpose of M and J is the anti-symmetric N-by-N matrix \begin{equation} J= \left(\begin{array}{cc} &I\\ -I& \end{array} \right) \end{equation} where I is the $\frac{N}{2}$-by-$\frac{N}{2}$ identity matrix. $USp(N)$ group has $\frac{N(N+1)}{2}$ generators. For $USp(4)$, the generators can be represented as Γ_{ab} which are defined through another set of matrices Γ_a by \begin{equation} \Gamma_{ab}=\frac{1}{2i}(\Gamma_a\Gamma_b-\Gamma_b\Gamma_a) \end{equation} and Γ_a themselves satisfy $\Gamma_a\Gamma_b+\Gamma_b\Gamma_a=2\delta_{ab}$. In this case we can verify that $J\Gamma_{ab}J=\Gamma_{ab}^T$ and $J\Gamma_{a}J=-\Gamma_{a}^T$. Moreover, $\sum_{ab}\Gamma_{ab}\Gamma_{ab}$ and $\sum_{a}\Gamma_{a}\Gamma_{a}$ are invariant under the fundamental representation of $USp(4)$, namely, $\sum_{ab}\Gamma_{ab}\Gamma_{ab}=U^\dagger\sum_{ab}\Gamma_{ab}\Gamma_{ab}U$ and $\sum_{a}\Gamma_{a}\Gamma_{a}=U^\dagger\sum_{a}\Gamma_{a}\Gamma_{a}U$ for any $USp(4)$ matrix U. My question is: for any even $N>2$, can we always find some Hermitian matrices Γ_a so that $J\Gamma_aJ=-\Gamma_a^T$ and $\sum_a\Gamma_a\Gamma_a$ is invariant under the fundamental representation of $USp(N)$ in the above sense? My conjecture to this question is that there are indeed such Γ_a, and more precisely, there are $N+1$ of them and they can still be used to derive the $\frac{N(N+1)}{2}$ generators of $USp(N)$ by $\Gamma_{ab}\propto\Gamma_a\Gamma_b-\Gamma_b\Gamma_a$. I appreciate if any one will check this conjecture and answer this question.

How I can make a proof to this conjecture if it is possible?

Is there someone who can show me the way helping me to proof this conjecture. If it's not open, at a least show me links or papers which to be helpful. Conjecture: Assume $c > 0$ and that an equilibrium point $\bar{z}$ of the difference equation: $$z_{n+1}=\frac{\alpha+z_{n}\beta+z_{n-1}\lambda }{A+Bz_{n}+cz_{n-1}}, \ n=0,1,\dots$$ is locally asymptotically stable. My question is: Show that $\bar{x}$ is a global attractor of all positive solutions of precedent equation. Note: this conjecture deal with the following simpler system: $$\begin{cases} x_{n+1}=\dfrac{\alpha_{1}}{y_{n}} \\ y_{n+1}=\dfrac{\alpha_{2}}{z_{n}} \\ z_{n+1}=\dfrac{\alpha_{3+}+\beta_{3}x_{n}+\sigma_{3}y_{n}+\lambda_{3}z_{n}}{A_{3}+B_{3}x_{n}+c_{3}y_{n}+D_{3}z_{n}}{}\end{cases} \quad n=0,1,\dots,$$ with non-negative parameters and non-negative initial conditions such that the denominators are always positive. any help is very welcom , thank you for your replies or any comments

I noticed a pattern, does this have a name?

First of all I am a programmer, not a mathematician, so I may articulate what I am trying to say very poorly. I was working with powers of 2 when I noticed a relationship I had never noticed before. Basically, if you look at the powers of 2, every other power of two can be added together make a multiple of 10. Furthermore, if the two numbers are 2^{10} and 2^8, adding them together will result in $2^7\cdot 10$. Put another way, $2^n + 2^{n-2} = 2^{n-3}\cdot 10$. Does this pattern have a name? I am attaching an image just to clarify my poor explanation. Thanks all! $$ \begin{matrix} & & \vdash & 20 & \dashv & \vdash & 160 & \dashv & \vdash & 1280 & \dashv \\ 1 & 2 & 4 & 8 & 16 & 32 & 64 & 128 & 256 & 512 & 1024 \\ & \vdash & 10 & \dashv & \vdash & 80 & \dashv & \vdash & 640 & \dashv \\ \end{matrix} $$

Why are there so many conjectures in number theory and comparatively less in others?

My question is that : Why are there so many conjectures in elementary number theory and comparatively less in others? This is particularly weird because every topic in maths should have its equal share of conjectures. On the other hand there are so many conjectures in number theory. Also (most of) these conjectures are so easy to state but literally impossible to prove. I thought of this question because I myself have two open conjectures in number theory.

Is it known or new?

Possible Duplicate: Starting digits of 2^n While I was randomly working with number patterns, I came along with some interesting pattern which seems to turn to a conjecture in fact. My conjecture can be stated as follows : For any number n there exists any number p such that the number np can be a power of two or 2^k (here the np doesn't represent product of n an p but the number p is placed to the right of n , for eg: if the number n is 11 then if p is 12 then np is 1112 not $11 \cdot 12$). For a practical demonstration let us consider a number 11 there exists any number you choose for example $805916207174113034 24$ (I have selected this number deliberately and I need to find an effective way of choosing numbers) such that if the number is placed to right of 11 it becomes $11805916207174113034 24$ which in turn makes the complete entity as 2^{70} . For a practical formulation, it took some time for me in the mathematical representation. My conjecture can be stated as " Consider a number N, then there exist a number P such that $$((N\cdot 10^{\lceil\,\log_{10} P\,\rceil})+P) \equiv 0\pmod{2^k} $$for some K. " Does this already exists or it is new? , if it exists please give me a reference. P.S : I have been trying for a proof, and I have a proof with me. Is it worth of publishing ? Thank you.

Conjecture about linear diophantine equations

I've been dabbling with linear Diophantine equations and came across a rather interesting pattern that I would like to conjecture as true but I have no idea how about to come up with a proof. Let $ax+by=c$ be the linear Diophantine equation such that $gcd(a,b)=1$. Obviously $1|c$ so there are solutions to the equation. If we consider only positive solution pairs (x,y) for the equation, then the number of ordered pairs that satisfy the equation is equal to (c/a)/b, rounded down to the nearest integer. Can anyone verify this by counterexample or by proof? Thanks

Is the conjecture $Per A $ is the largest eigenvalue of $\tilde{A}$ being solved?

Let A be a positive semidefinite matrix of order n. Is the conjecture $Per A $ is the largest eigenvalue of $\tilde{A}$ is being solved? Where $\tilde{A}$ is the matrix of order $n!\times n!$whose $(\sigma, \tau)^{th}$ entry is given by $\prod _{i=1}^{n} a_{{\sigma (i)}\tau(i)}$ $Per (A)=\sum _{\sigma\in S_n} \prod_{i=1}^{n} a_{i\sigma (i)}$ The conjecture has being proved for $n\leq 3$ in Bapat, R. B. ; Sunder, V. S. An extremal property of the permanent and the determinant. Linear Algebra Appl. 76 (1986), 153-163. Is there any further development in this problem?

What do you think about this conjecture?

Beforehand, please know that I'm a little bit of an amateur mathemitician, so this could be very wrong. But, I have tested it over and over and over again and it seems to be plausible, but there's still other things that I haven't tried that might possibly prove it wrong. That's why it's a 'conjecture' and not a 'theorem' or definitely not a 'law'. This conjencture involves functions. Any function. Let's say we have the function $f(x)$. Obviously, this doesn't mean I just multiply f by x, it is a function of x. But, what if there was a way to separate the two? Well, I came up with this simple equation as the base of this entire conjecture: $$f(x)=f*ƨx$$ where f is the function modifier and $ƨx$ is the terminal, meaning what the function modifier is in terms of. The first problem with this is $ƨx$. This is not a number or anything like that. It is its own concept, but it can be utilized in an equation. The second problem with this is f. How do he know that f is used in a function, and that it's not variable? Well, we don't know, unless it is blatantly defined as a function modifier. Usually, it is assumed that it's a function modifier, since it is in front of $ƨx$ and it's 'f', probably the most commonly used function modifier. Simply put, $f(x)$ is the same as a function modifier f multiplied by a value that has $ƨ$ in front of it. There is no operation that can add $ƨ$ in front of a value, $ƨ$ can only be taken from an actually function. Since: $$f(x) = f*ƨx$$ Therefore: $$f = f*ƨx/ƨx$$ and Also: $$ƨx = f*ƨx/f$$ With this conjecture, I can find the solution to some problems: find $g(x)$ in terms of a and b, assuming f and g are both function modifiers $$f(a)+f(b)=g(a+b)$$ Solve: $$f(a)+f(b)=g*ƨ(a+b)$$ $$(f(a)+f(b))/ƨ(a+b)=g$$ $$(f(a)+f(b))/ƨ(a+b)*ƨx = g*ƨx$$ $$(f(a)+f(b))ƨx/ƨ(a+b)=g(x)$$ Assuming $f/f=1$ (which it should) $$f/f *(f(a)+f(b))ƨx/ƨ(a+b)=g(x)$$ $$((f(a)+f(b))f*ƨx)/f*ƨ(a+b)=g(x)$$ $$((f(a)+f(b))f(x))/f(a+b)=g(x)$$ So my solution is: $$((f(a)+f(b))f(x))/f(a+b)=g(x)$$ Now after some tests, this proves to be right. I'll try to prove it here by saying $f(x)=2x-1$. This next problem will be similar to the last problem, excpet that $f(x)$ will now be defined. find $g(x)$, assuming f and g are both function modifiers. $f(x)=2x-1$ $$f(a)+f(b)=g(a+b)$$ Solve: $$((f(a)+f(b))f(x))/f(a+b)=g(x)$$ $$((2a-1)+(2b-1))(2x-1)/(2(a+b)-1)=g(x)$$ $$(2a-1+2b-1)(2x-1)/(2a+2b-1)=g(x)$$ $$(2a+2b-2)(2x-1)/(2a+2b-1)=g(x)$$ $$(4ax-2a+4bx-2b-2x+2)/(2a+2b-1)=g(x)$$ Now let's see if $g(x)$ really is equal to that... $$f(a)+f(b) = 2a-1+2b-1 = 2a+2b-2$$ Let's plug in $a+b$ into $g(x)$ to see if it's equal to $f(a)+f(b)$ $$((2a-1)+(2b-1))(2(a+b)-1)/(2(a+b)-1)=g(a+b)$$ The $2(a+b)-1$ in the nominator cancels out with the $2(a+b)-1$ in the denominator: $$(2a-1)+(2b-1)=g(a+b)$$ $$2a+2b-1=g(a+b)$$ And, it works! If you're thinking this, I also thought that it was a little suspicious that the nominator and the denominator cancel out, but considering I used $ƨx$ as the basis, that suspicion decreased. I've also used this conjecture to find another way to define the Gamma Function($\Gamma(x)$) using this definition: $$\Gamma(1-x)\Gamma(x)=\pi/sin(\pi*x)$$ $$\Gamma*ƨ(1-x)\Gamma*ƨ(x)=\pi/sin(\pi*x)$$ $$\Gamma^2*ƨ(1-x)ƨx)= \pi/sin(\pi*x)$$ $$\Gamma^2*ƨx=\pi/sin(\pi*x)ƨ(x-1)$$ $$\Gamma^2*ƨx*ƨx=\pi/sin(\pi*x)ƨ(x-1) *ƨx$$ $$(\Gamma*ƨx)^2=\pi/sin(\pi*x)ƨ(x-1) *ƨx$$ $$(\Gamma(x))^2=\pi/sin(\pi*x)ƨ(x-1) *ƨx$$ $$\Gamma(x)=sqrt((\pi*ƨx)/(sin(\pi*x)ƨ(x-1)))$$

However, this solution can not be used to directly utilize the function, since we don't know what $2x$ and $2(x-1)$ are, so it stays like that. Since it doesn't involve any other function, I can't multiply the numerator and denominator by a function operator. I've also used this conjecture to attempt to a find a way to define antiderivation. Now I COULD be very wrong on this because I don't really take into account the limit, which I have a feeling I should be, and I'm only assuming that h is still approaching 0 after all of this. $$f'(x)= lim(h>0) (f(x+h)-f(x))/h$$ $$f'(x)= lim(h>0) (f*2(x+h)-f*2(x))/h$$ $$f'(x)= lim(h>0) (f*(2(x+h)-2(x)))/h$$ $$f'(x)*h= lim(h>0) f*(2(x+h)-2(x))$$ $$(f'(x)*h)/(2(x+h)-2x) = lim(h>0) f$$ $$(f'(x)*h)/(2(x+h)-2x)*2x = lim(h>0) f*2x$$ $$(hf'(x)*2x)/(2(x+h)-2x) = lim(h>0) f(x)$$ $$ f(x) = lim(h>0)(hf'(x)*2x)/(2(x+h)-2x)$$ This is proven to be wrong, since h is not defined outside of the limit, but still, it shows the use of my conjecture. And so, this has been my conjecture. I don't know if it's solid, and I hope it doesn't get disproved (most likely will), but even if I'm redefining something that I didn't know existed, I hope it shows another way of thinking it.

Where $ax + b$ prime infinitely often, is $ax + b - 2$ semiprime at least once?

I'm trying to figure out a way to prove this: Given arithmetic progression $ax + b$ where a, b coprime and $ax + b$ is prime infinitely often, it is the case at least once that $ax + b - 2$ is semiprime when $ax + b$ is prime. I'm looking for a way either to prove it, or whether an existing theorem is already known from which this would follow. Stated another way, given arithmetic progression $ax + b$ where a, b coprime and $ax + b$ is prime infinitely often, it is at least once the case that $ax + b$ produces a cd + 2 prime, where c, d are prime. The list of cd + 2 primes is A063638 on OEIS. What we know: A Chen prime is a prime p such that $p + 2$ is either prime or semiprime. Chen proved in 1966 there are infinitely many of these. There are also infinitely many primes p such that $p - 2$ is specifically semiprime (not just prime-or-semiprime). Friedlander and Iwaniec proved this in their 2010 book. Note that I'm not asking whether $ax + b - 2$ is semiprime infinitely often. I just need it to happen once, that $ax + b$ is prime while $ax + b - 2$ is semiprime. A more specific version of the problem is this: Given arithmetic progression $P(P + 2)x + (P + 4)$ where P, $P + 2$ are twin primes, it is the case at least once that $P(P + 2)x + (P + 2)$, i.e., $(Px + 1)(P + 2)$ is semiprime when $P(P + 2)x + (P + 4)$ is prime. The deeper problem I'm trying to show is that it is the case at least once that $Px + 1$ is prime when $P(P + 2)x + (P + 4)$ [or, said another way, $(Px + 1)(P + 2) + 2$] is also prime. I'm trying to use Chen's theorem as a strategy to show this--- in other words, to show that $(Px + 1)(P + 2)$ must be semiprime at least once (and so, ergo, $Px + 1$ must be prime at least once) when $P(P + 2)x + (P + 4)$ is prime. All my efforts to prove one just leads to a tautology where I must assume the other first. Any thoughts, suggestions or help would be appreciated.

Does this $\zeta(s)$ identity have a name?

I have generalized the product from this thread: Let $s=2n+1$ for $n\ge1$, $$\zeta (s)=\frac{\zeta (2 s)}{\zeta (2)} \prod _{n=1}^{\infty } \frac{\sum _{i=0}^{s-1}(-p_n){}^i{(p_{n}-1)p_{n}^{s-2}}$$ This is a $\zeta(s)$ identity for each odd s. Does it have a name? I can only find $\zeta(3)$ in the literature.

Inequality in 3 variables (conjecture)

Let a, b, c be nonnegative real numbers such that $a+b+c=3$. If $0<k\leq 3+2\sqrt{3}$, then $$\frac{a}{b^2+k}+\frac{b}{c^2+k}+\frac{c}{a^2+k}\geq \frac{3}{1+k}$$ If $k=3+2\sqrt{3}$, then equality occurs if $a=b=c=1$ or $a=0$, $b=1-\sqrt{3}$ and $c=\sqrt{3}$ or any cyclic permutation thereof. This inequality can be found in Vasile Cirtoaje's Discrete inequalities, Volume 4 - page 61. Any idea for this inequality? Thank you!

A conjectured identity for tetralogarithms Li_4

I experimentally discovered (using PSLQ) the following conjectured tetralogarithm identity: $$720 \,\text{Li}_4\!\left(\tfrac{1}{2}\right)-2160 \,\text{Li}_4\!\left(\tfrac{1}{3}\right)+2160 \,\text{Li}_4\!\left(\tfrac{2}{3}\right)+270 \,\text{Li}_4\!\left(\tfrac{1}{4}\right)+540 \,\text{Li}_4\!\left(\tfrac{3}{4}\right)+135 \,\text{Li}_4\!\left(\tfrac{1}{9}\right)\\ \stackrel?=19 \pi ^4+30 \left(\pi ^2-\beta ^2\right) \left(10 \alpha ^2-12 \alpha \beta +3 \beta ^2\right)-30 \,\alpha ^2 \left(19 \alpha ^2-24 \alpha \beta +8 \beta ^2\right)\!,\\ \text{where $\alpha=\ln 2, \,\, \beta=\ln 3$.}$$ Numeric computations show that the absolute value of the difference between the left and right sides is smaller than 10^{-10^5}, so I believe the identity must hold exactly. Moreover, this is the simplest vanishing linear combination with integer coefficients of elementary terms and tetralogarithm values at rational points in the interval $(0,1)$ that I found. How can we prove it?

Sum involving the number of zeros of k

I'm currently interested in sums involving digit-functions. Especially, I'd like to calculate the following sum: $$ s=\sum_{k=1}^{\infty}{\frac{a_0(k)}{k\left(k+1\right)}} $$ Where $a_0(k)$ is the number of zeros in the base 10 representation of k. Normally, such sums can be tackled by considering products of the form $P(x,q)=\prod_{k=0}^{\infty}{\left(1+f_1(x)q^{10^k}+...+f_9(x)q^{9\cdot 10^k}\right)}$, but this approach seems not to work here, because the zero is a bit problematic. Numerically, it seems that $s=\frac{10+\gamma+\psi{(0.1)}}{9}$ where ψ is the digamma function.

If (a_n) is increasing and $a_n^{1/c^n}\to\infty$, then $\sum\frac1{a_n}$ is irrational?

I $\DeclareMathOperator\lcm{lcm}$am trying to generalise the result from this question: If (a_n) is increasing and $\lim_{n \to \infty} a_n^{1/2^n} = \infty$, show that $\sum_{k=1}^{\infty} 1/{a_n}$ is irrational and I try to prove that Conjecture (strong). If (a_n) is an increasing natural sequence and $c>1$ such that $a_n^{1/c^n}\to\infty$, then $\sum\frac1{a_n}$ is irrational. (Note that for $c\geq2$ we are done already.) Though I will also be happy if I only manage to prove that Conjecture (weak). If (a_n) is an increasing natural sequence such that $a_n^{1/c^n}\to\infty$ for all $1<c<2$, then $\sum\frac1{a_n}$ is irrational. In particular I am wondering whether $\sum_{n=0}^\infty\frac1{2^{2^n}+1}$ is irrational. (just curiosity) I'll summarize the proof in the linked question: It suffices to prove that $$\liminf_{k\to\infty}\sum_{n=k+1}^\infty\frac{\lcm(a_1,\ldots,a_k)}{a_n}=0;$$ we'll prove that in fact $$\liminf_{k\to\infty}\sum_{n=k+1}^\infty\frac{a_1\cdots a_k}{a_n}=0.$$ Let $a_n=b_n^{2^n}$ (so $b_n\to\infty$) and let r be such that $b_n\leq b_r$ for all $n\leq r$. Then $$\frac{a_1\cdots a_{r-1}}{a_{r+n}}=\frac{b_1^2\cdots b_{r-1}^{2^{r-1}}}{b_{r+n}^{2^{r+n}}}\leq\frac{b_r^{2+\cdots+2^{r-1}}}{b_{r+n}^{2^{r+n}}}\leq b_{r+n}^{2^n(2^r-2)-2^{r+n}}=b_{r+n}^{-2^{n+1}}.$$ Now choose r such that $b_n\geq M>1$ for all $n\geq r$ and we get $$\sum_{n=r}^\infty\frac{a_1\cdots a_{r-1}}{a_n}\leq\sum_{n=0}^\infty M^{-2^{n+1}}\leq\sum_{n=0}^\infty M^{-(n+1)}=\frac1M.$$ Because $M>1$ was arbitrary, we get $$\liminf_{k\to\infty}\sum_{n=k+1}^\infty\frac{\lcm(a_1,\ldots,a_k)}{a_n}=0.$$ It's not hard to see that this strategy (proving $\liminf_{k\to\infty}\sum_{n=k+1}^\infty\frac{\lcm(a_1,\ldots,a_k)}{a_n}=0$) does not work for $c<2$. For example for $a_n=2^{2^n}+1$ we have $\lcm(a_0,\ldots,a_k)=a_1\cdots a_k=2^{2^{k+1}}-1\approx a_{k+1}^2$ so even controlling the size of the first term is hopeless. What else can we do? Note: using the same strategy as in the linked question I was able to control the terms of $\sum_{n=k+1}^\infty\frac{a_1\cdots a_k}{a_n}$ (for suitable k) except the first $l-1$, where l is such that $c^l\geq c^{l-1}+1$. I'm not mentioning the proof here because controlling the first $l-1$ terms seems hopeless anyway.

Can the sum of 3 unique primes be expressed as the sum of 2 primes?

Let's consider the example, $$ 3 + 11 + 19 = 33 \\ 2 + 31 = 33 $$ we can see that there are cases where the sum of 3 primes be expressed as the sum of 2 primes. However, I couldn't find a case where a sum of 3 primes couldn't be expressed as a sum of 2 primes. Is there such a conjecture already in the world of mathematics? Or is there a counter example?

conjecture about primes and a certain q-series.

Using wolfram Mathematica ,I observed an interesting and surprising property concerning prime numbers and q-series which I could not prove.Yet there is strong evidence supporting it. I would be happy if anyone can find a counter-example.On the other hand,if it could turn out to be true,it would no doubt have amazing consequences in prime number theory. Let p be an odd prime and $$\frac{1}{(q;q^4)_{\infty}^p}=\prod_{n=0}^{\infty}\frac{1}{(1-q^{4n+1})^p}=1+\sum_{n=1}^{\infty} \phi(n)\,q^n$$ with the usual convention $$(a;q)_{\infty}=\prod_{k=0}^{\infty} (1-aq^{k})$$ then $$\phi(n)\equiv 0\pmod{p}$$ is true for all natural numbers $\{1,2,3,\dots\}$ except at multiples of p. For example, $$\frac{1}{(q;q^4)_{\infty}^3}=1 + 3q +6q^2 + \color{brown}{10}q^3 + 15q^4 + 24q^5+ \color{brown}{37}q^6+\dots$$ $$\frac{1}{(q;q^4)_{\infty}^5}=1 + 5q +15q^2 + 35q^3 + 70q^4 + \color{brown}{131}q^5+ 235q^6+405q^7+\dots$$ Note: $\phi(n)$ is just a notation I chose as a matter of personal taste. Can any one try to prove the conjecture or rather verify it by numerical methods,thanks in advance.

connection between odd primes and a certain q-series

I posed a conjecture about odd primes and a certain q-serieshere.I thought it would be more appropriate ,if I could ask the converse of the aforementioned problem . Is p an odd prime iff $$\prod_{n=0}^{\infty}\frac{1}{(1-q^{4n+1})^p}=1+\sum_{n=1}^{\infty}\phi(n)\,q^n$$ such that $$\phi(n)\equiv 0\pmod{p}$$ is true for all natural numbers $n\in\mathbb{N}$ except at multiples of p. I've experimentally verified the conjecture for many values of p,and it seems to hold.Independent verification would be greatly appreciated.This conjecture seems to point to a deep connection between primes and modular forms,which I was not able to prove.Outlining a proof or connection between the particular q-series above and odd primes will be appreciated.

a conjectured new generating function of narayana's sequence

In the 14th century ,an Indian mathematician T.V Narayana came up with a sequence now named after him.The sequence satisfies the recurrence $$a_{n}=a_{n-1}+a_{n-3}$$ Starting with $a_{0}=a_{1}=1$, and $a_{2}=2$ hence, $a_n = 1, 1, 2, 3, 4, 6, 9, 13,\dots$ I would like to conjecture a new generating function for narayana's sequence a_{n}. Given $$\psi\Big(q\Big)=\cfrac{1}{1+q-\cfrac{(q^2)}{1+q^3+\cfrac{q^2(1-q)(1-q^3)}{1+q^5-\cfrac{q^3(1+q^2)(1+q^4)}{1+q^7+\cfrac{q^4(1-q^3)(1-q^5)}{1+q^9-\ddots}}}}}$$ How can we show that $$\psi\Big(q\Big)= \sum_{n=0}^\infty (-1)^{n} a_{n}q^n = 1 -1q +2q^2-3q^3+4q^4-6q^5+\dots$$ is true,such that the functional equation holds $$\psi\Big(q\Big)=\frac{1}{q}\psi\Big(\frac{1}{q}\Big)$$

Infinitely many correct solutions to equation?

I conjecture that there are infinitely many correct solutions to this equation: (Where we are assuming $a,b \in \Bbb{N}$) $$a!+1=b^2$$ I chose to list the first three solutions below: $4!+1=5^2$ $5!+1=11^2$ $7!+1=71^2$ and so on... Could I have a proof or disproof of my conjecture? (I don't even know where to start)

an interesting q-series and a certain continued-fraction

My aim is to find a rigorous proof of the following conjectured identity.Given $$1+q+q^2-q^4-q^5+q^7+q^8-q^{10}-q^{11}+\ddots=\cfrac{1}{1-q+\cfrac{(q^3)}{1-q^3+\cfrac{q^2(1+q)(1+q^3)}{1-q^5+\cfrac{q^3(1+q^2)(1+q^4)}{1-q^7+\cfrac{q^4(1+q^3)(1+q^5)}{1-q^9+\ddots}}}}}$$ The exponents on the left-hand side $${1,2,4,5,7,8,\ddots}$$ are positive integers not divisible by 3. How do we show that, the identity is true? Independent verification and attempts at proving/disproving the result are very welcome.

A relation related with odd perfect numbers

It is easy to prove, using the relation $\prod_{d\mid n}d=n^{\sigma_0(n)/2}$ holds for $n\geq 1$ where $\sigma_0(n)$ is the number of divisors, the following Proposition. The integer $n\geq 1$ is a perfect number if and only if $$2^{\sigma_0(n)}\cdot\left(\prod_{d\mid n}d\right)^2=\left(\sum_{d\mid n} d\right)^{\sigma_0(n)}$$ Thus it is easy to prove, noting the sum of divisors as $\sigma(n)$, that if $n\geq 1$ is an odd perfect number then $$\sigma\left(\sigma(n)^{\sigma_0(n)}\right)=\left(2^{\sigma_0(n)+1}-1\right)\cdot\sigma\left(\prod_{d\mid n}d^2\right)$$ My attempt was prove the converse statement, Question. Prove that if an integer $n\geq 1$ satisfies $$\sigma\left(\sigma(n)^{\sigma_0(n)}\right)=\left(2^{\sigma_0(n)+1}-1\right)\cdot\sigma\left(\prod_{d\mid n}d^2\right)$$ then n is odd and a perfect number (this is, an odd perfect number), or give a counterexample. Thanks in advance.

A false conjecture by Goldbach

In 1752 Goldbach send this conjecture to Euler: "Every odd integer can be written in the form $p+2a^2$ where p is a prime or 1 and a is a natural number (can be even 0)." This conjecture turned out to be false and my book asks me to prove that 5777 cannot be

written in such manner. What I did is simply noted that if exists such p it must be of the form $5777-2a^2$ and so a mustn't be greater than 53. Then I simply checked that for every values of a from 0 to 53 p is not prime. Btw this is a very tedious way to prove this and may in a test I wouldn't be able to do this so I was wondering if there was any shorter way? (or my book just wanted me to make a lot of calculations for some reason.)

Conjectured value of a harmonic sum $\sum_{n=1}^\infty\left(H_n-\,2H_{2n}+H_{4n}\right)^2$

There is a known asymptotic expansion of harmonic numbers H_n for $n\to\infty$: $$\begin{align}H_n&=\gamma+\ln n+\sum_{k=1}^\infty\left(-\frac{B_k}{k\cdot n^k}\right)\\ &=\gamma+\ln n+\frac1{2n}-\frac1{12n^2}+\frac1{120n^4}-\frac1{252n^6}\,+\,\dots,\end{align}\tag1$$ where B_k are Bernoulli numbers. We can take a linear combination of harmonic numbers to cancel constant and logarithmic terms, compensate for $O(n^{-1})$ term, and get the following series that is possible to evaluate in a closed form (e.g. using generating function): $$\sum_{k=1}^\infty\left(H_n-\,2H_{2n}+H_{4n}-\frac1{8n}\right)=\frac18-\frac\pi{16}.\tag2$$ Rather than compensating for $O(n^{-1})$ term, we can take a series with alternating signs, that is also possible to evaluate in a closed form: $$\sum_{n=1}^\infty\,(-1)^n\,\Big(H_n-\,2H_{2n}+H_{4n}\Big)=\frac{3\pi}{16}-\frac\pi{4\sqrt2}-\frac{\ln2}8.\tag3$$ Generalizing, we can consider two families of series: $$\mathcal A_m=\sum_{n=1}^\infty\,(-1)^n\,\Big(H_n-\,2H_{2n}+H_{4n}\Big)^m,\tag4$$ $$\mathcal B_m=\sum_{n=1}^\infty\Big(H_n-\,2H_{2n}+H_{4n}\Big)^m,\tag5$$ and try to evaluate them in a closed form. So far I have the following conjectured result: $$\large\sum_{n=1}^\infty\Big(H_n-\,2H_{2n}+H_{4n}\Big)^2\stackrel{\normalsize\color{gray}?}=\frac\pi8-\frac\pi{16}\,\ln2-\frac{\pi^2}{96}+\frac3{16}\,\ln^22-\frac{G}{4},\tag{$\diamond$}$$ where G is the Catalan constant. Could you please help me to prove this result and, possibly, find other values of $\mathcal A_m,\mathcal B_m$?

A proof that $\frac{(2\phi)^n-(-1)^n}{\phi^{2n}-(-1)^n}\cdot\left(2^n-\phi^n\right)\cdot\sqrt5\in\mathbb Q$ for all $n\in\mathbb Z$

During computation of some series (with help of a CAS), at an intermediate step I encountered an expression, that after dropping non-essential parts looks like this:$$\mathcal E_n=\frac{(2\phi)^n-(-1)^n}{\phi^{2n}-(-1)^n}\cdot\left(2^n-\phi^n\right)\cdot\sqrt5$$ where $\phi=\frac{1+\sqrt5}2$ is the golden ratio (for $n=0$ take a limit and let $\mathcal E_0=0$). Although it is not immediately obvious from its form, it appears that $\mathcal E_n$ takes only rational values for all integer n. So far it is only an observation, and I am asking you to help me to find a proof. For example, it could be a recurrence relation with only rational coefficients.

Can the determinant of an integer matrix with k given rows equal the gcd of the $k\times k$ minors of those rows?

I'm interested if the following is true: Let $n> k\geq1$ be integers, let $A\in\mathbb Z^{k\times n}$ and denote the $\binom nk$ $k\times k$ minors of A by $A_1,\ldots,A_N$. Then the equation $$\left|\begin{array}{c}A\\\hline X\end{array}\right|=\gcd(A_1,\ldots,A_N)$$ always has a solution $X\in\mathbb Z^{n-k\times n}$. This is a generalisation of Can the determinant of an integer matrix with a given row be any multiple of the gcd of that row? (which is the case $k=1$). For $\style{text-decoration:line-through}{k=n}$ and $k=n-1$ the above conjecture is also (obviously) true. Note that, as in the linked question, finding the minimal positive value of that determinant is equivalent to finding the minimal hypervolume of an n-dimensional simplex whose vertices are in an integer lattice and $k+1$ vertices are fixed. Idea: The case $\gcd(A_1,\ldots,A_N)=1$ may follow from Elementary proof that if A is a matrix map from $\mathbb{Z}^m$ to $\mathbb Z^n$, then the map is surjective iff the gcd of maximal minors is 1

A series summation

How should I calculate the following expression? \begin{equation} T\sum_{n=-\infty}^\infty\frac{1}{\sqrt{k^2+(2\pi nT)^2}}-\int_{-\infty}^\infty\frac{d\omega}{2\pi}\frac{1}{\sqrt{k^2+\omega^2}} \end{equation} Since neither of the two terms converges, so what this expression really means is \begin{equation} \lim_{N\rightarrow\infty}\left(T\sum_{n=-N}^N\frac{1}{\sqrt{k^2+(2\pi nT)^2}}-\int_{-2\pi NT}^{2\pi NT}\frac{d\omega}{2\pi}\frac{1}{\sqrt{k^2+\omega^2}} \right) \end{equation} The answer to the above expression must be a function of k/T, say it is $f\left(\frac{k}{T}\right)$. I think this function f has pretty good properties so that the following integral converges: \begin{equation} \int_0^\infty dk\cdot k\cdot f\left(\frac{k}{T}\right) \end{equation} I suspect the final answer to the above integral is $\pi T^2\ln\left(\frac{1+\sqrt{5}}{2}\right)$ up to a factor of 2.

Does this conjecture about prime numbers exist? If n is a prime, then there is exist at least one prime between n^2 and n^2+n.

I made an observation on prime numbers, want to check if any conjecture already exist or not? I am a computer programmer by profession and I am interested in number theory. As like many others I am intrigued by prime numbers. Based on my observation, I found following to be true If n is a prime, then there is exist at least one prime between n^2 and n^2+n I am not sure if this conjecture already exist? I tried searching in the internet but did not find any exact conjecture. I would like to know, first of all is my above statement is correct? if not, can any provide me with a counter example where it fails. If this statement is correct, does this conjecture already proposed by someone?

Understanding Erdös Discrepancy Conjecture $\left| \sum_{i=1}^k x_{i\cdot d} \right| > C$ for random series of -1 and 1

In today's newspaper NRC from The Netherlands a two-page article was dedicated to computer-aided mathematical proofs (sorry, paid link and in Dutch). Interesting in itself, but as an example it used the partial proof for divergence of the series consisting of a random distribution of -1 and 1. The Wikipedia lemma about Erdös conjecture shows this formula: $$\left| \sum_{i=1}^k x_{i\cdot d} \right| > C$$ But I have trouble understanding that in common English and applying it to the text of the article, which translates as: given an infinite sequence of -1 and 1, take a finite set of terms at equal distance, i.e. the first, third and fifth, or the fifth, tenth and fifteenth term. Add all those terms together. How far can they differ from 0? Erdös conjecture: infinitely far. My misunderstanding comes from combining infinite, random and finite. I think that if the sequence is random, then any given finite set can potentially exist of only 1 or only -1, meaning that the difference to zero is (potentially) equal to the amount of terms taken. The article further explains that Boris Konev and Alexei Lisitsa have proven that within the first 1161 terms, the discrepancy is always at least 3. But I can easily come up with a sequence that alternates on exactly the numbers taken, which would obviously result in a possible discrepancy of at most 1 for at least some series or slices. From the link, quote: The proof that the computer came up with proves, the two researchers claim, "that no sequence of length 1161 and discrepancy 2 exists." This seems contradictory, but no-one in the articles I found seem to wonder about this, and given that it requires so much research, I assume I simply misunderstand the problem. I assume I am misunderstanding the problem, but can anybody explain me where I am going wrong?

A number-theory question on the deficiency function $2x - \sigma(x)$

Let $\sigma(x)$ be the sum of the divisors of a (positive) integer x. (For example, $\sigma(2) = 1 + 2 = 3$.) Define the deficiency function $D(x)$ to be the number $$D(x) = 2x - \sigma(x).$$ Let y be a (positive) integer. Now I compute the difference: $$D(xy) - D(x)D(y) = 2xy - \sigma(xy) - (2x - \sigma(x))(2y - \sigma(y))$$ $$=2xy - \sigma(xy) - 4xy + 2y\sigma(x) + 2x\sigma(y) - \sigma(x)\sigma(y)$$ $$=-2xy - 2\sigma(x)\sigma(y) + 2y\sigma(x) + 2x\sigma(y) + (\sigma(x)\sigma(y) - \sigma(xy))$$ $$=2(x - \sigma(x))(\sigma(y) - y) + (\sigma(x)\sigma(y) - \sigma(xy)).$$ This is because I want to compare $D(xy)$ and $D(x)D(y)$. Note that, in general we have $$2(x - \sigma(x))(\sigma(y) - y) \leq 0$$ and $$\sigma(x)\sigma(y) - \sigma(xy) \geq 0.$$ Lastly, observe that if we have $D(xy) = D(x)D(y)$, then it follows that $$2(\sigma(x) - x)(\sigma(y) - y) = \sigma(x)\sigma(y) - \sigma(xy).$$ My question is: Will it be possible to prove either $$D(xy) \leq D(x)D(y)$$ or

$$D(x)D(y) \leq D(xy),$$ subject to additional assumptions, if necessary? [Updated Sept. 8, 2015] If x and y are relatively prime (i.e., $\gcd(x, y) = 1$), then it follows that $D(xy) \leq D(x)D(y)$. By the contrapositive, we have the equivalent implication: "If $D(x)D(y) < D(xy)$, then $\gcd(x, y) > 1$." Finally, I conjecture that if the equation $D(xy) = D(x)D(y)$ is true, then either x or y is 1, or both x and y are powers of 2.

conjectured identity of the product of two theta functions

Looking into the discussion in this post, I was naturally led to consider the following general identity Given the two well known jacobi theta functions, namely $\theta_2(q)=\sum_{n=-\infty}^\infty q^{(n+1/2)^2}$ and $\theta_3(q)=\sum_{n=-\infty}^\infty q^{n^2}$ where $q=e^{2 \pi i\tau}$, $|q|\lt1$ It is then conjectured that the following identity is true $\frac{\cfrac{2\,q^{\frac{1}{2}}}{1-q^2+\cfrac{q^2(1-q^2)^2}{1-q^6+\cfrac{q^4(1-q^4)^2}{1-q^{10}+\cfrac{q^6(1-q^6)^2}{1-q^{14}+\ddots}}}}}{\cfrac{1}{1-q+\cfrac{q(1+q)^2}{1-q^3+\cfrac{q^2(1+q^2)^2}{1-q^5+\cfrac{q^3(1+q^3)^2}{1-q^7+\ddots}}}}}=\theta_2(q^2)\,\theta_3(q^2)$

Conjectured closed form for $\operatorname{Li}_2\!\left(\sqrt{2-\sqrt3}\cdot e^{i\pi/12}\right)$

There are few known closed form for values of the dilogarithm at specific points. Sometimes only the real part or only the imaginary part of the value is known, or a relation between several different values is known: [1][2][3][4][5][6]. Discovering a new identity of this sort is always of a great interest. I numerically discovered the following conjectured closed form and now am looking how to prove it: $$\operatorname{Li}_2\!\left(\sqrt{2-\sqrt3}\cdot e^{i\pi/12}\right)=\operatorname{Li}_2\!\left(\tfrac12+i\left(1-\tfrac{\sqrt3}2\right)\right)\stackrel{\color{gray}?}=\\\frac{23\pi^2}{288}-\frac18\ln^2\!\left(2+\sqrt3\right)+i\left[\frac{2\;\!G}3+\frac{\pi^2}{12\sqrt3}-\frac\pi{24}\ln\left(2+\sqrt3\right)-\frac1{8\sqrt3}\psi^{\small(1)}\!\left(\tfrac13\right)\right]$$ If you have got any ideas please share them. G is the Catalan constant, and $\psi^{\small(1)}(z)$ is the trigamma function. To respond questions in comments: my approach to find closed forms like this is to evaluate the expression with hundreds or sometimes thousands digits of precision and then use integer relation algorithms to find a matching linear combination with rational coefficients from a pool of candidate terms. The tricky part is that the pool cannot be too big, otherwise the algorithms begin to work extremely slowly or fail and produce false positives, so I need some intuition to select a restricted set of candidates that are likely to appear in a closed form I'm looking for. I usually select candidates from known closed forms of similar expressions, or from known closed forms of integrals that contain the expression in question along with other simpler terms (its "siblings"). Sometimes I also add some variations of existing terms, e.g. multiply them by a simple irrational coefficient like $\sqrt3$, or replace occurences of $\ln2$ with $\ln3$. When I find a matching linear combination, I verify it with much higher precision (usually tens or hundreds of thousand of decimal digits) to reduce chances that it is an accidental close but non-exact expression.

a conjectured continued fraction for $\tan\left(\frac{z\pi}{4z+2n}\right)$

Given a complex number $\begin{aligned}\frac{z}{n}=x+iy\end{aligned}$ and a gamma function $\Gamma(z)$ with $x\gt0$, it is conjectured that the following continued fraction for $\displaystyle\tan\left(\frac{z\pi}{4z+2n}\right)$ is true $$\begin{split}\displaystyle\tan\left(\frac{z\pi}{4z+2n}\right)&=\frac{\displaystyle\Gamma\left(\frac{z+n}{4z+2n}\right)\Gamma\left(\frac{3z+n}{4z+2n}\right)}{\displaystyle\Gamma\left(\frac{z}{4z+2n}\right)\Gamma\left(\frac{3z+2n}{4z+2n}\right)}\\&=\cfrac{2z}{2z+n+\cfrac{(n)(4z+n)}{3(2z+n)+\cfrac{(2z+2n)(6z+2n)}{5(2z+n)+\cfrac{(4z+3n)(8z+3n)}{7(2z+n)+\ddots}}}}\end{split}$$ Corollaries: By taking the limit(which follows after abel's theorem) $$ \begin{aligned}\lim_{z\to0}\frac{\displaystyle\tan\left(\frac{z\pi}{4z+2}\right)}{2z}=\frac{\pi}{4}\end{aligned}, $$ we recover the well known continued fraction for π $$\begin{aligned}\cfrac{4}{1+\cfrac{1^2}{3+\cfrac{2^2}{5+\cfrac{3^2}{7+\ddots}}}}=\pi\end{aligned}$$ If we let $z=1$ and $n=2$,then we have the square root of 2 $$\begin{aligned}{1+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\ddots}}}}}=\sqrt{2}\end{aligned}$$ Q: How do we prove rigorously that the conjectured continued fraction is true and converges for all complex numbers z with $x\gt0$? Update:I initially defined the continued fraction $\displaystyle\tan\left(\frac{z\pi}{4z+2}\right)$ for only natural numbers,but as a matter of fact it holds for all complex numbers z with real part greater than zero.Moreover,this continued fraction is a special case of the general continued fraction found in this post.

about conjecture "every finite nonabelian p-group admits a noninner automorphism of order p"

by "The Kourovka Notebook. Unsolved Problems in Group Theory" there is a strong conjecture asserts that every finite nonabelian p-group admits a noninner automorphism of order p. What about finite abelian p-group? Is there a finite abelian p-group without noninner automorphism of order p? If yes can we for example by changing "order p" in conjecture make it for all finite p-group?

a conjectured continued-fraction for $\displaystyle\cot\left(\frac{z\pi}{4z+2n}\right)$ that leads to a new limit for π

Given a complex number $\begin{aligned}\frac{z}{n}=x+iy\end{aligned}$ and a gamma function $\Gamma(z)$ with $x\gt0$, it is conjectured that the following continued fraction for $\displaystyle\cot\left(\frac{z\pi}{4z+2n}\right)$ is true $$\begin{aligned}\displaystyle\cot\left(\frac{z\pi}{4z+2n}\right)=\frac{\displaystyle\Gamma\left(\frac{z}{4z+2n}\right)\Gamma\left(\frac{3z+2n}{4z+2n}\right)}{\displaystyle\Gamma\left(\frac{z+n}{4z+2n}\right)\Gamma\left(\frac{3z+n}{4z+2n}\right)}=\cfrac{2z+2n}{2z+n+\cfrac{(0z-n)(4z+3n)}{3(2z+n)+\cfrac{(2z+0n)(6z+4n)}{5(2z+n)+\cfrac{(4z+n)(8z+5n)}{7(2z+n)+\cfrac{(6z+2n)(10z+6n)}{9(2z+n)+\ddots}}}}}\end{aligned}$$ Or in gauss's notation $$\begin{aligned}\displaystyle\cot\left(\frac{z\pi}{4z+2n}\right)=-\frac{1}{2z+2n}\underset{m=0}{\overset{\infty}{\mathbf K}}\frac{((2m-2)z+(m-2)n)((2m+2)z+(m+2)n)}{((2m+1)(2z+n)}\end{aligned}$$ Corollaries: 1):let $z=1$ and $n=2$,then we obtain a beautiful continued fraction for square root 2 $$\begin{aligned}{-1+\cfrac{3}{2+\cfrac{\frac{(-1)(5)}{(1)(3)}}{2+\cfrac{\frac{(1)(7)}{(3)(5)}}{2+\cfrac{\frac{(3)(9)}{(5)(7)}}{2+\cfrac{\frac{(5)(11)}{(7)(9)}}{2+\ddots}}}}}=\sqrt{2}\end{aligned}$$ 2):However the most interesting case(for me at least),occurs when we take the limit to zero $$\begin{aligned}\lim_{z\to0}\cfrac{z(z+1)}{2z+1+\cfrac{(0z-1)(4z+3)}{3(2z+1)+\cfrac{(2z+0)(6z+4)}{5(2z+1)+\cfrac{(4z+1)(8z+5)}{7(2z+1)+\cfrac{(6z+2)(10z+6)}{9(2z+1)+\ddots}}}}}=\frac{1}{\pi}\end{aligned}$$ yielding a new limit for π from which one obtains the first few convergents $\begin{aligned}0,\frac{3}{8},\underline{\frac{5}{16}},\frac{15}{47},\frac{7}{22}},\frac{1365}{4288},\frac{3015}{9472},\frac{1575}{4948},\ddots\end{aligned}$. Where the underlined convergents appear in the stern-brocot tree for $\pi $ associated to its simple continued fraction. Q: Is the conjectured continued fraction true (for all complex numbers z with $x\gt0$)? Update:I initially defined the continued fraction $\displaystyle\cot\left(\frac{z\pi}{4z+2}\right)$ for only natural numbers,but as a matter of fact it holds for all complex numbers z with real part greater than zero.This continued fraction is one special case of the general continued fraction found here.

Proving the existence of consecutive quadratic residues modulo $p>5$ by means of Pell's equation

When I read Existence of Consecutive Quadratic residues I thought we might be able to prove the existence of non-zero consecutive quadratic residues modulo a prime $p>5$ using the theory of Pell-type equations: if $d>1$ is a quadratic residue modulo p, then any solution (x,y) to $x^2-dy^2=1$ gives rise to consecutive quadratic residues (x^2,dy^2) modulo p. It seems a promising method to me; the only problem lies in making sure that x and y aren't divisible by p. Can we show that for any prime $p>5$, there exists a quadratic residue $d>1$ modulo p and a solution (x,y) to $x^2-dy^2=1$ s.t. $p\nmid x,y$?

Does the following equation have any solutions in $\mathbb{N}$?

Let $\mathbb{N}$ be the set of positive integers. The function $\sigma(N)$ gives the sum of the divisors of N. My question is: Does the following equation have any solutions for $x \in \mathbb{N}$? $$\sigma(3x + 1) = 4x + 1$$ Notice that $3x + 1$ must be deficient, and that if we allow $x = 0$, then it is a (trivial) solution. Furthermore, suppose that $3x + 1 = p^{\alpha}$, where p is prime. Then we have $$\sigma(3x + 1) = \frac{p^{\alpha+1} - 1}{p - 1} = \frac{4(p^{\alpha} - 1)}{3} + 1 = 4x + 1,$$ from which we obtain $$3(p^{\alpha+1} - 1) = 4(p - 1)(p^{\alpha} - 1) + 3(p - 1).$$ Simplifying and collecting like terms, we get $$0 = p^{\alpha+1} - 4p^{\alpha} + p + 4.$$ Rewriting the last equation, we have $$(p^{\alpha} + 1)(4 - p) = 8.$$ As $p^{\alpha} + 1 \geq 3$, we have the possibilities $$(p^{\alpha} + 1, 4 - p) \in \{(4,2),(8,1)\}.$$ Both of them are impossible under the given constraints. Consequently, $\omega(3x + 1) \geq 2$, where $\omega(y)$ is the number of distinct prime factors of y. (That is, $3x + 1$ must be composite.) Lastly, I tried checking for equality (in the range $0 \leq x \leq 100$) using a spreadsheet, and found only the solution for $x=0$. I am therefore compelled to predict that: The equation $\sigma(3x + 1) = 4x + 1$ does not have any solutions for $x \in \mathbb{N}$.

Number of Magic squares and their applications

A magic square is a square array of numbers consisting of the distinct positive integers $1, 2, ..., n^2$ arranged such that the sum of the n numbers in any horizontal, vertical, or main diagonal line is always the same number I was wondering if the numbers of magic squares of order n is still a conjecture (For a general n) ? And I have some elementary questions regarding the magic squares. (1) What is the smallest n for a magic square ? I guess for $n=1$ we just have one 1×1 matrix $[1]$ (2)And for $n=2$, They don't exists !! (right) (3)For $n=3$ we have 8 different magic squares and so on. Now my question is, after $n=3,4$ The numbers of magic squares grows rapidly, and I want to know if there is a systematic way to get those numbers or does it remain to be a conjecture ? Is there some interesting applications where those magic squares are used ? I have a project to do on combinatorics and I was thinking of considering this (what do you guys think ?) It will be interesting to try some code and algorithms on it too. I would also love if someone knows a good resource or papers on those magic squares.

4 Divides x Proofs of conjectures

Hi there I'm working on a set of problems and I'm having some difficulty proving and disproving these examples. I know that #1 is essentially (There exists K where [x=4k]) I'm lost after that. I'm not sure about 2 or 3 I believe that 2 is false and 3 is true but I don't know how to prove or disprove formally. Any advice would be wonderful thank you! Define what it means for a number to be divisible by 4, that is, the concept 4 | x. Answer: There exists k where [x=4k] Determine whether the following conjecture is true or false. If it is true, prove it, otherwise construct a counterexample to disprove it. Conjecture 1. Let x and y be arbitrary integers. If 4 | (x-y), then 4 | (3x+y). Determine whether the following conjecture is true or false. If it is true, prove it, otherwise construct a counterexample to disprove it. Conjecture 2. For integers x and y, if 4 | x and 8 | y, then 8 | (x+y).

Iterated $\sigma^k(n)$, excluding the possibility that primes $p|\sigma^t(n)$, $t< k$ divides an odd perfect number n

Let $m\geq 1$ an integer and $\sigma(m)=\sum_{d|m}$ the sum of positive divisors function. A positive integer is said to be perfect if and only if $\sigma(n)=2n$. We have that $\sigma(m)$ is a multiplicative function (see this site or [1]), thus we have the known Fact. If n is an odd perfect number then $\sigma(\sigma(n))=6n$. Proof. We don't know if there are odd perfect numbers, is an unsolved problem, but assuming the existence then $\sigma(2n)=\sigma(2)\cdot\sigma(n)=3\cdot 2n=6n$, since $gcd(2,n)=1$, and this is the end of the proof. Hypothesis to work. In this post we assume that $n=n_1$ is the first odd perfect number, if there is one. Now we define iterated of the sum of divisor function, as is ususal $$\sigma^k(m)=\sigma(\sigma^{k-1}(m))=\sum_{b|\sigma^{k-1}(m)}b$$ for integers $k>1$ and $\sigma^1(m)=\sigma(m)$. Hypothetical algorithm. And I compute terms of the sequence $$\sigma^k(n)$$ always excluding the possibility that an prime previously computed in the factorization of all previous terms of the sequence $\sigma^t(n)$, are $t<k$, divides n. (Please if you want explain my idea in a better sense or words, too the question bellow feel free to edit, thanks.) Thus my Question. For the first odd perfect number $n=n_1$ where we can find/estimate the barrier of using this algorithm? Thanks in advance. I say, $\sigma^3(n)=8\cdot 3\cdot n$ and I assume to add as hypothesis that $3\nmid n$. Now I compute using that the sum of positive divisor function is multiplicative another time... $\sigma^4(n)=\frac{2^4-1}{2-1}\cdot 4\cdot 2n=8\cdot 3\cdot 5\cdot n$. Well Tochard theorem say that perhaps is possible that there are odd perfect numbers of the form $12\lambda+1$, but perhaps I cannot assume yet that $5\nmid n$ (looking the barrier yes I assume and add the hypothesis that $5\nmid n$). Going to the behaviour of the sum of divisor function, and the fact that if n_1 exists, then can I apply the Fundamental Theorem of the Arithmetic and Euler's Theorem for odd perfect numbers to bound the barrier of use in previous algorithm? References: [1] Wikipedia pages for Divisor function and Odd Perfect Numbers.

Is it true/known/important that $(\log p_n)/n$ is nonincreasing, where p_n is the nth odd prime number?

First thing first, I would like to apologize in advance for my poor knowledge of Maths and English. I'm an Italian student and after asking to all the mathematicians and Maths teachers in my town, I hope that the internet might help me regarding the following conjecture. Conjecture: If p_{n} is the nth odd prime, then $$ \frac{\log_{10}p_{n}}{n} \geq \frac{\log_{10}p_{n+1}}{n+1}. $$ To date, I've tested it for the first 64k prime numbers. My questions are: -Does it deserve to be shown to other people/tried to prove, or is it just "one among thousands"? -If it's important, who could I show it to? -If it isn't important, what makes some conjectures noteworthy?

Is $p(p + 1)$ always a friendly number for p a prime number?

Let $\sigma(x)$ denote the sum of the divisors of x. We call the ratio $I(x) = \sigma(x)/x$ as the abundancy index of x. A positive integer N is friendly if there exists a positive integer $M \neq N$ such that $I(M) = I(N)$. My question is the following: Is $Z = p(p + 1) = p\sigma(p)$ always a friendly number for p a prime number? Note that $$\gcd(Z, \sigma(Z)) = \gcd(p(p + 1), (p + 1)\sigma(p + 1)) \geq p + 1 \geq 3,$$ so that Greening's Theorem fails to establish solitude. OEIS sequence A074902 lists the following as friendly: $$6, 12, 30, 56, 132$$ but does not list 182 and 306, for example.

Why is proving that 10 is solitary considered very difficult?

The title says it all. We denote the sum of the divisors of x by $\sigma(x)$. The ratio $I(x)=\sigma(x)/x$ is called the abundancy index of x. If $I(m)=I(n)$, then $\{m,n\}$ is called a friendly pair. A number which is not a member of a friendly pair is called solitary. So: Why is proving that 10 is solitary considered very difficult? Is there no (known) partial converse to Greening's Theorem (i.e., $\gcd(N, \sigma(N)) = 1 \implies N$ is solitary)? What is the main obstruction? OEIS sequence A014567 contains the following statement from Dean Hickerson: It is easy to show that if N and $\sigma(N)$ are relatively prime then N is solitary. But the converse is not true; for example, 18, 45, 48 and 52 are solitary.

Probably also 10, 14, 15, 20, 22 and many others are solitary, but I do not think that will ever be proved. Update (November 11, 2015): I am aware of the paper Does Ten Have a Friend?, which gives some necessary conditions for a number to be a friend of 10. This question is essentially an offshoot of the following earlier MSE posts: Can distinct odd perfect numbers $N = {p^k}{m^2}$ share the same Euler factor p^k? If $\sigma(N) = aN + b$, where $\gcd(a, b) = 1$, does it follow that at least one of N's factors is solitary? Is $p(p + 1)$ always a friendly number for p a prime number?

V3-018589 | MSE-1522912

If $\gcd(Z,\sigma(Z))=1$ and $1<N=Z\sigma(Z)$, is N always friendly?

This question is a generalization / offshoot of this earlier MSE post: If $\gcd(Z,\sigma(Z))=1$ and $1<N=Z\sigma(Z)$, is N always friendly? Here, $\gcd(a,b)$ is the greatest common divisor of a and b, and $\sigma(x)$ is the sum of the divisors of x. Note that $$\gcd(N ,\sigma(N))=\gcd(Z\sigma(Z),\sigma(Z\sigma(Z)))=\gcd(Z\sigma(Z),\sigma(Z)\sigma(\sigma(Z))) \geq \sigma(Z) > 1$$ where the last inequality follows from $1<N=Z\sigma(Z)$, so that Greening's Theorem fails to establish that N is solitary. (However, this does not conclusively prove that N is friendly.) For an example: Consider $Z = 2^{p-1}$ where p and $2^p - 1$ are primes. There does not seem to be a sequence in OEIS for Numbers n such that $\gcd(n,\sigma(n))=1$ and $n\sigma(n)$ is friendly.

Twin primes sums conjecture

I have found an interesting conjecture between twin primes sums. I don't know if it is already described by someone else. I have checked in internet, but I didn't find any mention of such conjecture. Could you please tell me if the following conjecture is well known for mathematicians or not? Let's take twin prime pair 11 and 13 and do the sum: 11+13=24 Now find out sums of two prime numbers which gives the result 24. 5+19=24 7+17=24 You can see that sums 5+19 and 7+17 contain twin primes 5, 7 and 17, 19. Sum of twin primes 11 + 13 can be written by sum of combinations of twin primes 5, 7 and 17, 19. Another example: Let's take sum of twin prime pair 17, 19: 17+19=36 Its sum can be written with using of other twin primes 5, 7 and 29, 31 as: 5+31=36 7+29=36 We can define twin prime sums conjecture as follow. Let’s p and q are twin prime numbers; q=p+GAP. For each p+q = a+b = c+d. Where a, b, c, d are prime numbers, where a, c and b, d are prime pairs where c=a+GAP ; d=b-GAP. For twin primes sums conjecture GAP is equal to 2. Twin prime sums conjecture doesn’t work for prime pairs p, q equals (3, 5), (5, 7), (197, 199), (347, 349). I have checked the first 100 000 twin primes. The largest checked twin prime pair was 18409199 + 18409201 = 1019 + 36817381 = 1021 + 36817379. It has been found that there are exceptions of p, q for which this conjecture doesn’t work. For sums 3+5; 5+7; 197+199; 347+ 349 it doesn’t exist a, b and c, d which fulfill conjecture. If twin prime sum conjecture is true then there are unlimited twin prime pairs, because it shows that each twin prime pair sum can be written by sum of combination of smaller and larger twin prime pairs. For twin primes gap between p,q is equal to 2. I have found that similar conjecture works also for larger even gaps. Example for GAP equals 6 23+29=52 We can see that GAP between primes 23 and 29 is equal to 6. 29 - 23 = 6. Now we will find sums of other primes which have equal sum to 52. 5+47=52 11+41=52 We have combination of primes 5, 11 and 41, 47. We can see that GAP between those primes is equal to 6, (11 - 5 = 47 - 41 = 6) and is same as the GAP between primes 29 and 23 . I have also checked this generalized conjecture for primes below 100 000 and even gaps below 100. All of the gaps have few exception pairs p, q for which conjecture doesn’t work, but in major amount of cases conjecture works and for sum of primes with gap we can find another two sums of prime pairs with same gap.

With $s(n)=\sum_{k=1}^n n \bmod k$, can be justified that $\forall\epsilon>0$ let us $\lim_{n\to\infty}\frac{s(n-1)}{\epsilon+s(n)}=1?$

Denoting as $$s(n)=\sum_{k=1}^n n \bmod k$$ the sum of remainders function (each remainder is defined as in the euclidean division of integers $n\geq 1$ and k). See [1] for example. For examples $s(1)=0$ and $$s(6)=0+6\bmod4+6\bmod5+0=2+1=3.$$ After some computational experiments I am interesting in Question. Can you prove or refute (too are welcome heuristics) that $\forall\epsilon>0$ $$\lim_{n\to\infty}\frac{s(n-1)}{\epsilon+s(n)}=1?$$ Similarly that $\forall\epsilon>0$ $$\lim_{n\to\infty}\frac{s(n)}{\epsilon+s(n-1)}=1?$$ Thanks in advance, it seems curious, and I believe that previous is a strong condition in the sense that its proof could be easy, or well in the sense that find a counterexample could be easy (I am refering to the presence of such ϵ). I don't know if previous exercises are in the literature. There are formulas involving this function (see [1] for example) with the sum of divisors function $\sigma(n)=\sum_{d\mid n}d$, that holds for each integer $n>1$ $$\sigma(n)+s(n)=s(n-1)+2n-1,$$ and a companion formula that can be deduced inductively from previous (see too in [1]). Well my experiements aren't the bests, neither I have enough resolution to see the limit, but there is a difference when I plot $\frac{s(n)}{s(n-1)}$ ($n\geq 5$) or $\frac{\sigma(n)}{\sigma(n-1)}$ or $\frac{\phi(n)}{\phi(n-1)}$, where this last is Euler's totient function. References: [1] Math Overflow, How to calculate the sum of remainders of N? https://mathoverflow.net/questions/195325/how-to-calculate-the-sum-of-remainders-of-n I've read the notes from two authors Spivey and Cross.

Among any $2n$ consecutive integers below n^2+2n at least one has no prime divisor less than n?

What is your idea about my conjecture? Consider a sequence of $2n$ consecutive natural numbers, all the terms less than $n^2 + 2 n$. Then there exists at least one number in the sequence which is not divisible by any prime less than or equal to n.

Density of odd numbers in a sequence relating base 2 and base 3 expansion

Define the function $$f(4n)=6n+1\\ f(4n+1)=6n+2\\ f(4n+2)=6n+3\\ f(4n+3)=6n+5$$ and the sequence $u_0=2$, $u_{k+1}=f(u_k)$. Let $d_1\le d_2$ be the lower and upper asymptotic density of odd numbers in u_k. Since $f(n)$ is odd for even n, no two consecutive terms can be even so obviously $d_1\ge 1/2$. Experimentally, it seems reasonable to conjecture $d=d_1=d_2=2/3$. Heuristically, when n is odd, $f(n)$ has "probability 1/2" to be even, so we get this Markov chain: which is consistent with $d=2/3$. But can we prove rigorously that the heuristic works, that is that u_k is "random enough" for this to be true? Failing that, a sharper lower bound on d_1 could still be an interesting result. (One approach could be to let $a_k=1$ if u_k is even and 0 otherwise, and examine the probabilities of the p-bit subwords $(a_k,\dots,a_{k+p-1})$. Unfortunately every Fibonacci word, that is one not containing the pattern 11, seems to appear infinitely frequently in a_k. This is consistent with the Markov chain model.) PS: If you're wondering, the problem arose from this question. Response to comments: Someone suggested to work modulo some larger number, such as 12. The problem with this approach is that if the input is considered mod $2^a 3^b$, the output will only be known mod $2^{a-1} 3^{b+1}$ so you're not going to be able to say much about the behavior of f when iterating more than a times. And it seems that $010101\dots$ can always appear as a subword of a_k, so you won't be able to prove anything non-trivial about the density by proving something about the density after k iterations starting from an arbitrary state (that is, by examining f^k for bounded k). The first few terms are 2, 3, 5, 8, 13, 20, 31, 47, 71, 107, 161, 242. The sequence grows as $\Theta((3/2)^n)$. Interestingly, notice how closely the first few terms match the Fibonacci sequence (which can be explained by how close $3/2$ is to the golden ratio and by the fact that modulo 2, neither sequence contains the pattern 00).

The four runner problem/conjecture

I've recently read here the following problem, called « four-runner problem » : Suppose four runners (represented by labeled spheres) run around a circular track. Their speeds are constant positive rationals $v_1<v_2<v_3<v_4$. At time 0, all the runners are together at the starting gate; shortly after, they are arranged in the order $\{1, 2, 3, 4\}$, counting from the starting gate. The order changes to $\{4, 1, 2, 3\}$ when runner 4 passes the starting gate. Then either runner 3 passes the starting gate, runner 4 laps runner 1, or the two events happen at the same time, giving possible orders $\{3, 4, 1, 2\}$, $\{1, 4, 2, 3\}$, or $\{3, 1, 2, 4\}$. [...] The answer to this question is unknown: which rates generate all 24 possible orders? For three runners, all six orders are achieved if and only if the two slower rates do not add up to the fast rate. For instance, I found that the rates $0.1 < 0.2 < 0.61 < 0.9$ generate the 24 possible combinations. I would like to know where to find more information on that problem. Are there some research articles about it? I didn't find anything, even for the case with 3 runners (which does not seem obvious to me). Thank you in advance!

A conjecture about the prime counting function

Using this lemma it can be proved that $\Delta(m,n)=\pi(m\cdot n)-\pi(m)\cdot\pi(n)+1$ (where π is the prime counting function) is a function $\Delta:\mathbb N\times\mathbb N\to\mathbb N$. Reformulated conjecture: Given $m\in\mathbb N,m>2$, then $n\in \mathbb N$ is an odd prime if $\Delta(m,n-1)>\Delta(m,n)<\Delta(m,n+1)$ and if n is an odd prime then $\Delta(m,n-1)\ge\Delta(m,n)\le\Delta(m,n+1)$. The conjecture is tested for $m,n<3000$. Counterexample: 5879 is a prime, but $\Delta(5878,5879)=1525672>\Delta(5878,5878)=1523414$

Are all totient values of Fibonacci Numbers distinct?

This question was inspired while I was seeing how certain recurrence relations would behave when I applied Multiplative Functions. Let F_{n} be a sequence for which $F_{1}=1,F_{2}=1$, and $F_{n}=F_{n-1}+F_{n-2}$. For any $n,m>8$, is it always true that $\phi(F_n)$ is not equal to $\phi(F_m)$, when ϕ is the Euler Totient Function? A case when n divides m appeared be rather simple. $n|m$ would imply $F_{n}|F_{m}$. Then let F_{m} be F_{n} multiplied by k. $\phi(F_{m}) \ge \phi(F_{n})\phi(k)$. $F_{n+1}=F_{n}+F_{n-1}<2F_{n}$, and $F_{n+2}=2F_{n}+F_{n-1}>2F_{n}$. Thus k may never be equal to 2. Therefore, $\phi(k)$ will always be greater than 1 implying $\phi(F_{m})=\phi(k)\phi(F_{n})>\phi(F_{n})$. Therefore, for the case when n divides m, $\phi(F_m)$ is always not equal to $\phi(F_n)$. However, other cases proved to be rather difficult, such as proving $\phi(F_n) \neq \phi (F_{n+1})$. Can anybody prove or disprove this question? Any Help would be greatly appreciated.

Conjecture $\sum_{m=1}^\infty\frac{y_{n+1,m}y_{n,k}}{[y_{n+1,m}-y_{n,k}]^3}\overset{?}=\frac{n+1}{8}$, where $y_{n,k}=(\text{BesselJZero[n,k]})^2$

While solving a quantum mechanics problem using perturbation theory I encountered the following sum $$ S_{0,1}=\sum_{m=1}^\infty\frac{y_{1,m}y_{0,1}}{[y_{1,m}-y_{0,1}]^3}, $$ where $y_{n,k}=\left(\text{BesselJZero[n,k]}\right)^2$ is square of the k-th zero of Bessel function J_n of the first kind. Numerical calculation using Mathematica showed that $S_{0,1}\approx 0.1250000$. Although I couldn't verify this with higher precision I found some other cases where analogous sums are close to rational numbers. Specifically, after some experimentation I found that the sums $$ S_{n,k}=\sum_{m=1}^\infty\frac{y_{n+1,m}y_{n,k}}{[y_{n+1,m}-y_{n,k}]^3} $$ are independent of k and have rational values for integer n, and made the following conjecture $\bf{Conjecture:}\ $ for $k=1,2,3,...$ and arbitrary $n\geq 0$ $$\sum_{m=1}^\infty\frac{y_{n+1,m}y_{n,k}}{[y_{n+1,m}-y_{n,k}]^3}\overset{?}=\frac{n+1}{8},\\ \text{where}\ y_{n,k}=\left(\text{BesselJZero[n,k]}\right)^2. $$ How one can prove it? It seems this conjecture is correct also for negative values of n. For example for $n=-\frac{1}{2}$ one has $y_{\frac{1}{2},m}=\pi^2 m^2$, $y_{-\frac{1}{2},k}=\pi^2 \left(k-\frac{1}{2}\right)^2$ and the conjecture becomes (see Claude Leibovici's answer for more details) $$ \sum_{m=1}^\infty\frac{m^2\left(k-\frac{1}{2}\right)^2}{\left(m^2-\left(k-\frac{1}{2}\right)^2\right)^3}=\frac{\pi^2}{16}. $$

Conjecture for the maximum number of rooms.

The puzzle I have is essentially this, but for n rows.For this instance of $n=5$, quick tallying reveals the answer to be 21. For $n=4$, it is 13. For $n=3$, it is 7. For $n=2$ it is 3. And for $n=1$, it is obviously 1. I conjectured a formula to calculate the maximum number of rooms: $n^2 - n +1$. I have tested this formula upto $n=7$ and it works. (I don't want to test anymore, too lazy) Now it is my understanding that all conjectures must be proven, but I don't know how to prove mine. I'm thinking induction, but as I haven't formally learnt it yet, I'm not well versed in induction. I'd appreciate it if you could show me a proof. It need not be induction. Thanks :)

Sum and product of k real numbers > 0 is unique?

Can we prove that $\sum_{i=1}^k x_i$ and $\prod_{i=1}^k x_i$ is unique for $x_i \in R > 0$? I stated that conjecture to solve CS task, but I do not know how to prove it (or stop using it if it is false assumption). Is the pair of Sum and Product of array of k real numbers > 0 unique per array? I do not want to find underlying numbers, or reverse this pair into factorisation. I just assumed that pair is unique per given set to compare two arrays of equal length to determine whether numbers inside with possible multiplicities are the same. The order in array does not matter. 0 is discarded to give meaningful sum and product. At the input I get two arrays of equal length, one of which is sorted, and I want to determine if the elements with multiplicities are the same, but I do not want to sort the second array (this will take more than linear time, which is the objective). So I thought to make checksums, sum and product seemed unique to me, hence the question. For example: I have two arrays: v=[1,3,5,5,8,9.6] and the second g=[9.6,5,3,1,5,8]. I calculate sum = 31.6, and product = 5760. For both arrays, since one is sorted version of another. And now I calculate this for b=[1,4,4,5,8,9.6], sum is 31.6 but product is 6144. So I assumed that if both sum and product are not the same for two given arrays, than the element differs. Getting back to question, I am thinking that the pair {sum, product} is the same for all permutations of array (which is desired), but will change when elements are different (which is maybe wishfull thinking).

Recreational conjecture on factoring groups

Consider the following: For a group G with identity e, define $s: G \to \mathbb{N} \cup \{ \infty \}$ by $s(g) = \min \{ k \in \mathbb{N} : g^{k} = e \}$, where $ \min \emptyset = \infty$. Moreover, let $\Theta(G) = \sup \{ s(g) : g \in G \}$. Refer to G as bounded if there exists $N \in \mathbb{N}$ such that $g^{N} = e$ for all $g \in G$. We see that G is bounded iff $\Theta(G) < \infty$. If $\Theta(G) $ is finite, then $g^{\Theta(G) !} = e$; if $\Theta(G) = \infty$, then for every N there exists $g \in G$ for which $s(g) > N$, so $g^{N} \neq e$. Moreover, any group of order n is bounded. To see this, the claim is made that $s(g) \leq n$ for all $g \in G$. To see this, consider the set $ \{ g, g^{2}, \ldots, g^{n + 1} \}$. By pigeonhole, there exist $1 \leq i < j \leq n + 1$ such that $g^{i} = g^{j}$, so $g^{j - i} = e$; then $s(g) \leq j - i \leq n$. Thus $\Theta(G) \leq n$. Initially, I conjectured that a set was bounded off it was finite, considering the multiplicative group $\{ e^{iq} : q \in \mathbb{Q} \}$, where $s(g)$ is always finite, but unbounded. Then I dismissed this considering $G = \mathbb{Z}_{2}^{I}$, where I is an infinite indexing set and $\Theta(G) = 2$. I revised this to the claim that a group G is bounded if and if it can be written as a product $G = \prod_{i \in I} H_{i}$ of finite groups for some index set I, where $\sup \{ \# H_{i} : i \in I \} < \infty$. I believe I know how to show any factoring of G into finite groups would satisfy this, but I can't show that every bounded group is factorable into finite groups, i.e. can't show there doesn't exist a bounded group which cannot be expressed as a product of finite groups. Is this correct? If so, how might I show it? If not, is there a counterexample? Thanks.

Integral $\int_0^\infty\Big[\log\left(1+x^2\right)-\psi\left(1+x^2\right)\Big]dx$

I found this intriguing integral: $$\int_0^\infty\Big[\log\left(1+x^2\right)-\psi\left(1+x^2\right)\Big]dx\approx0.84767315533332877726581...$$ where $\psi(z)=\partial_z\log\Gamma(z)$ is the digamma. A lookup in ISC+ (in "advanced" mode) returned a possible closed form $\frac\pi2\Big[\zeta\!\left(\frac12\right)+2\Big]$ that seems to agree with the numeric value of the integral when calculated to a higher precision. Any ideas how to prove it?

Fibonacci Numbers and the Harmonic Series

$$\sum_{k=1}^{n} \frac{1}{k}=H_n=\frac{p_n}{q_n}$$ Where p_n,q_n are coprime intergers. The first few values for p_n+q_n are $2,5,7,37,197,69,504,1041,9649$. When are p_n+q_n Fibonacci numbers? Due to the inequality, $\ln(n+1)<H_n<\ln(n)+1$, $\ln(n+1)q_n<p_n<(\ln(n)+1)q_n$. Therefore, this would imply that $(\ln(n+1)+1)q_n<p_n+q_n<(\ln(n)+2)q_n$. However, $\frac{\ln(n)+2}{\ln(n+1)+1}<\phi$ where ϕ is the golden ratio. Though this is sloppy logic, because of this I thought it was likely are few cases where p_n+q_n are Fibonacci numbers. The only solutions appeared to be $2,5$. Any help would be appreciated.

Is there a typo in the formula or does my GAP-package sglppow fail?

This site deals with group formulas for prime powers p^k for $k\le 7$. The formula for $k=7$ seems to be wrong. I compared the results with GAP and the formula is off by 2453 for $p=13,17,19,23$ and 29. Moreover the lcm of the numbers $3,4,5,7,8,9$ is not 360, but 2520 and as I understood the column "modulus relative ...", the value 2520 should be right. The values for $p=7$ and $p=11$ coincide with the given formula. Does anyone know the correct formula ? Does GAP give the wrong values, or is the given formula wrong ? The formula given in the link is $$gnu(p^7)=3p^5+12p^4+44p^3+170p^2+707p+2455$$ $$+(4p^2+44p+291)gcd(p-1,3)+(p^2+19p+135)gcd(p-1,4)$$ $$+(3p+31)gcd(p-1,5)+4gcd(p-1,7)+5gcd(p-1,8)+gcd(p-1,9)$$ What I get with GAP : gap> LoadPackage("sglppow"); LieRing a package for working with Lie rings by Serena Cicalo' and Willem de Graaf ---------- Loading LiePRing 1.8 by Michael Vaughan-Lee and Bettina Eick ---------- ---------- Loading SglPPow 1.0 by Michael Vaughan-Lee and Bettina Eick ---------- true gap> gnup7:=p->3*p^5+12*p^4+44*p^3+170*p^2+707*p+2455+ > (4*p^2+44*p+291)*Gcd(p-1,3)+(p^2+19*p+135)*Gcd(p-1,4)+ > (3*p+31)*Gcd(p-1,5)+4*Gcd(p-1,7)+5*Gcd(p-1,8)+Gcd(p-1,9); function(p) ... end gap> p:=Filtered([7..100],IsPrimeInt); [7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43, 47, 53, 59, 61, 67, 71, 73, 79, 83, 89, 97] gap> r:=List(p, x -> [x, gnup7(x), NrSmallGroups(x^7)]); [[7, 113147, 113147], [11, 750735, 750735], [13, 1600573, 1598120], [17, 5546909, 5544456], [19, 9380741, 9378288], [23, 23316851, 23314398], [29, 71271069, 71268616], [31, 98488755, 98486302], [37, 233043067, 233040614], [41, 384847485, 384845032], [43, 485930975, 485928522], [47, 751588475, 751586022], [53, 1356370173, 1356367720], [59, 2299880351, 2299877898], [61, 2710679045, 2710676592], [67, 4306310927, 4306308474], [71, 5734323819, 5734321366], [73, 6578172579, 6578170126], [79, 9721485395, 9721482942], [83, 12413061671, 12413059218], [89, 17537591045, 17537588592], [97, 26866372821, 26866370368]] gap> List(r, x -> [x[2]-x[3]]); [[0], [0], [2453]] gap>

Group conjecture

Conjecture: Given a finite group G and a subset $A\subset G$. Then $\{A,A^2,A^3,\dots\}$ is a group iff $\forall n\in \mathbb N: |A^n|=|A^{n+1}|$. Given that the composition between the subsets $A,B\subset G$ is $A\cdot B=\{g\in G|\exists a\in A\exists b\in B:g=a\cdot b\}$. Example: suppose that $N\subset G$ is a normal subgroup, then the cosets $\{Ng,Ng^2,...\}$ have the same cardinality and constitutes a group, while for random sets the cardinality seems to grow when multiplying: { 3412 2143 4321 1234 } { 2143 1234 } nswap pnormal . -1 ok { 3412 2143 4321 1234 } { 2143 1234 } pquotient set. {{3412,4321},{2143,1234}} ok { 4321 3412 } go ok gen. {4321,3412} ok gen. {2143,1234} ok gen. {4321,3412} ok ndrop ok { 2431 2341 } go ok gen. {2431,2341} ok gen. {4132,3142,4312,3412} ok gen. {1234,1243,3214,4213,1324,1423,3124,4123} ok gen. {2413,2314,3421,4321,1423,1324,2341,2431,2143,2134,3241,4231,1243,1234} ok gen. {4123,3124,4321,3421,2143,2134,4132,3142,4213,3214,4231,3241,3412,4312,1432,1342,2413,2314,2431,2341} ok gen. {4231,3241,1234,1243,3214,4213,1432,1342,1324,1423,2134,2143,2314,2413,4123,3124,4321,3421,4132,3142,4312,3412} ok gen. {3412,4312,2314,2413,2341,2431,2143,2134,4321,3421,3241,4231,1342,1432,3142,4132,1234,1243,3214,4213,1324,1423,3124,4123} ok gen. {4123,3124,3142,4132,3412,4312,1432,1342,3214,4213,2413,2314,3421,4321,1423,1324,2341,2431,2143,2134,3241,4231,1243,1234} ok ndrop ok

Does the antipode of a f.d. Hopf algebra have finite order

In a lecture I have heard that the antipode of a finite-dimensional Hopf algebra is conjectured to be finite, and that this has only been proven in characteristic 0 by Larson and Radford in 1988. I couldn't find such a result (only stronger statements that the antipode has order 2 or 4 in some nice situations). But I have found the older paper D. E. Radford, The antipode

of a finite-dimensional Hopf algebra over a field has finite order. Bull. Amer. Math. Soc. 81 (1975), no. 6, 1103--1105 which gives a proof sketch (which I cannot verify) that the conjecture is true in general. What is the actual status of the conjecture? Related (weaker) question: Is the antipode of a finite-dimensional Hopf algebra always invertible? If so, is there an easy proof for this statement, which one can understand without much background? Takeuchi has constructed an infinite-dimensional Hopf algebra whose antipode is not invertible.

Rational solutions for $\sin(n)$ in radians

This is completely for my own curiosity. Does $y = \sin(n)$ have rational solutions for n, an integer number of radians. I know that this is strange because usually integers are only used in degrees. I know that there will be convergent sub series of n's to any rational number in $[-1,1]$. Would we ever get an algebraic integer? It would have something like $$ e^\left(n i\right)=e^\left(\frac{n}{\pi}\pi i\right) $$ I suspect that it will never have a rational solution but I don't know how to prove it.

Conjecture: $\lim_{x\to\infty} \frac{256}{163x}\sum_{n=1}^{\lfloor x\rceil} |\sin n|=1$

I conjecture: $$\lim_{x\to\infty} \frac{256}{163x}\sum_{n=1}^{\lfloor x\rceil} |\sin n|=1$$ Is this provable? If this is false, then can I have a function f such that: $$\lim_{x\to\infty} f(x)\sum_{n=1}^{\lfloor x\rceil} |\sin n|=1$$

Does this conjecture in 1-d real analysis seem reasonable

Hello I am currently trying to prove a result and I have basically whittled it down to showing the following is true. Let $I\subset\mathbb{R}$ be an interval and fix $\alpha>1$ real number. Fix $x\in I$ and suppose $f:I \rightarrow \mathbb{R}$ is a strictly increasing function. Let $\{x_k\}$ be a sequence contained in I such that $x_k \neq x$ for all k and $x_k \rightarrow x$. Now suppose that the limit $\lim_{k \to \infty} \frac{f(x_k)-f(x)}{f(x+\alpha(x_k-x))-f(x)} $ exists and is equal to l. Then $l \neq 0$. To me it makes sense that this is true. Since f is strictly increasing it can't do anything too mental near x, since f is locally bounded both must converge to 0 and surely the numerator can't dominate the denominator enough for the limit to be zero. My argument in trying to prove it so far goes: It is clear that $0\leq l \leq 1$ so suppose $l=0$. Then since f is locally bounded we deduce that $f(x_k)-f(x) \to 0$. Since f is strictly increasing we deduce that f must be continuous (here we either get full continuity or left continuity or right continuity depending on the sequence x_k but I don't think this really matters much) at x. Then I've been playing around with functions and this seems to hold for everything but I don't really know how to proceed.

If b is an odd composite number and $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q$ is a prime number, what happens when $q = 2^{r + 1} - 1$?

(Note: An improved version of this question has been cross-posted to MO.) Let $\sigma(X)$ be the sum of the divisors of X. For example, $\sigma(2) = 1 + 2 = 3$, and $\sigma(4) = 1 + 2 + 4 = 7$. My question is: If b is an odd composite and $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q$ is a prime number, what happens when $q = 2^{r + 1} - 1$ (with $r \geq 1$)? Without the restriction on $q = 2^{r + 1} - 1$ being prime, I only know that $M = {2^r}{b^2}$ must be an even almost perfect number. (That is, it must satisfy $\sigma(M) = 2M - 1$.) I guess my question can be rephrased as follows: (1) If b is an odd composite, how often is $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q$ a prime number? (2) If b is an odd composite, and $\dfrac{b^2 - 1}{\sigma(b^2) - b^2} = q$ is a prime number, how often is q a Mersenne prime?

Does the Descartes number $D = 198585576189$ have a friend?

Let $\sigma(X)$ be the sum of the divisors of X, and denote the abundancy index $\sigma(X)/X$ by $I(X)$. If the equation $I(X) = r/s$ has no solution $X \in \mathbb{N}$, then r/s is said to be an abundancy outlaw. A number $Y \neq X$ is said to be a friend of X if $I(Y) = I(X)$. If a number Z does not have a friend, then it is said to be solitary. Greening's Theorem provides a sufficient but not necessary condition for a number to be solitary - namely, $\gcd\left(Z, \sigma(Z)\right) = 1 \implies Z$ is solitary. Here is my first question: (1-A) Does the Descartes number $D = 198585576189$ have a friend? Greening's Theorem fails to establish the number's solitude, because $$\gcd\left(D, \sigma(D)\right) = \gcd(198585576189, 426027470778) = \gcd\left({3^2}\cdot{7^2}\cdot{{11}^2}\cdot{{13}^2}\cdot{{19}^2}\cdot{61},{2}\cdot{3^3}\cdot{7}\cdot{13}\cdot{{19}^2}\cdot{31}\cdot{61}\cdot{127}\right) = {3^2}\cdot{7}\cdot{13}\cdot{{19}^2}\cdot{61} = 18035199.$$ Here is a way to rephrase my first question: (1-B) Is there a number $\overline{D} \neq 198585576189$ such that $$I(\overline{D}) = I(D) = \dfrac{{2}\cdot{3}\cdot{31}\cdot{127}}{{7}\cdot{{11}^2}\cdot{13}} = \dfrac{23622}{11011}?$$ Notice that 11011 is a palindrome (in base-10). Note also that 23622 is almost a palindrome (again, in base-10). This brings me to my second question: (2) Is the ratio $22622/11011$ an abundancy index or outlaw?

Can we capture the definition to be a Mersenne prime in an identity only involving the arithmetic function $S(n)=\sum_{k=1}^n\text{nmod k}$?

Let $S(n)=\sum_{k=1}^n\text{nmod k}$ the sum of remainder function, denoting $\sigma(n)$ as the sum of divisors function, it is know that for each $n>1$ $$S(n)-S(n-1)=2n-1-\sigma(n),$$ is as curiority an statement due to Lucas. Too it is know the identities that we can show for perfect nubmers, almos perferct numbers and prime numbers. See here. On the other hand it is know some attempts and theorems that look capture the definition of a sequence only in terms of an arithmetic function. My attempt was use previous function to show that Fact 1. If $m=2^p-1$ is a Mersenne prime then $$m\left(S\left(m\right)-S\left(m-1\right)\right)+S\left(\frac{m-1}{2}\right)-S\left(\frac{m+1}{2}\right)=m(m-2).$$ $$$$ The proof is show that then $m(m-2)-\left(m-(2^p-1)\right)=m(m-2)$. Notice that the second summand $-\left(m-(2^p-1)\right)$ is zero. Fact 2. Conversely if $m>3$ is an odd integer and safisties the equation in previous fact, then this satisfies $$m^2+\sigma\left(\frac{m+1}{2}\right)=m\sigma(m),$$ and thus denoting $m=2k-1$ one has $$4k^2+1-4k+\sigma(k)=(2k-1)\sigma(2k-1).$$ $$$$ Computational facts. I don't know if previous identity involving the sum of divisor function for odd integers is in the literature. My computations were that only obtain Mersenne primes when I use a computer. On the other hand as I've said there are relationships between the formulas for primes and almost perfect numbers, for this reason I am confusing. Also I know equation, a relation problem, here in spanish, PROBLEMA 55, page 156-157, where * means unsolved, for which I don't know how clarify this $$$$ Question. Can you get a closed formula involving only the sum of remainders function, that isn't superfluous, and does capture the definition of Mersenne primes? Is this $$m\left(S\left(m\right)-S\left(m-1\right)\right)+S\left(\frac{m-1}{2}\right)-S\left(\frac{m+1}{2}\right)=m(m-2)?$$ If you can show an odd integer m, as counterexample for this last equation I will apprecite, since I don't made computations for this equation. Can you clarify my doubts about if my computations were empty by comparision with the cited literature? Thanks in advance.

I think I've found all roots to $f_k(x)=\sum_{j=1}^k x^j-x^{-j}$ for any k - how to prove it?

Conjecture: The set of unique roots of $$f_k(x)=\sum_{j=1}^k x^j-x^{-j} \;,\;\; x \not=0$$ is given by $e^{i \pi \phi_k}$, where $$\frac{1}{2}\phi_k=\{0, \frac{1}{2}, \underbrace{\frac{\pm1}{k+1},\frac{\pm1}{k},\frac{\pm2}{k+1},\frac{\pm2}{k},\frac{\pm3}{k+1},...}_\text{$k-1$ elements} \}$$ Q: If true, how can this be proven? I unfortunately don't have much experience with proving stuff (I'm a physicist), so any insights would greatly appreciated! This may very well be some lemma, but I thought it might be useful since Mathematica wasn't able to solve this kind of equation for $k>12$. Note that the roots of f_k are equivalent to the roots of $f_{k,n}=\sum_{j=1}^k x^{n+j}-x^{n-j}$. Also, if $x \not = 1$ $f_k=\frac{x^{-k}(x^{k}-1)(x^{k+1}-1)}{x-1}$. The process through which I reached this conjecture (btw, sorry if "conjecture" sounds pretentious, but I didn't know what else to call it) is described below. Just to get an overview, here's one way of writing out $f_k=0$: \begin{array}{c|c} k & \\ \hline 1 & x^2-1=0\\ 2 & x^4+x^3-x-1=0 \\ 3 & x^6+x^5+x^4-x^2-x-1=0 \\ \vdots &\vdots \end{array} I noticed a high degree of regularity when plotting the solutions. The solutions to the first 12 k are shown below, plotted in the complex plane. $\hskip1.4in$ (I have no idea why Mathematica doesn't recognize -1 as a solution to f_1, but oh well) I now organized the solutions such that one might see a pattern: If one looks at the list of the roots for $k\in \{1,...,12\}$, they can all be written as a phase only, $e^{i \pi \phi}$, where ϕ is some rational number. For instance, the roots of f_2 are $\{1,e^{\pm \frac{2}{3} i \pi},-1\}$ so $\phi_2=\{0,\pm \frac{2}{3},1 \}$. I'm assuming that this pattern continues indefinitely. All $0<\phi<1$ appears with both a positive and a negative sign, and all sets of solutions include $\phi=\{0,1\}$. The non-negative and non-trivial (0 and 1) values for ϕ_{k} for $k\in \{1,...,12\}$ are listed here (written as reduced fractions, going from smallest to largest values): \begin{array}{c|c} k & \phi_k \\ \hline 2 & \frac{2}{3}\\ 3 & \frac{1}{2} \;\; \frac{2}{3}\\ 4 & \frac{2}{5} \;\; \frac{1}{2} \;\; \frac{4}{5}\\ 5 & \frac{1}{3} \;\; \frac{2}{5} \;\; \frac{2}{3} \;\; \frac{4}{5}\\ 6 & \frac{2}{7} \;\; \frac{1}{3} \;\; \frac{4}{7} \;\; \frac{2}{3} \;\; \frac{6}{7}\\ 7 & \frac{1}{4} \;\; \frac{2}{7} \;\; \frac{1}{2} \;\; \frac{4}{7} \;\; \frac{3}{4} \;\; \frac{6}{7}\\ 8 & \frac{2}{9} \;\; \frac{1}{4} \;\; \frac{4}{9} \;\; \frac{1}{2} \;\; \frac{2}{3} \;\; \frac{3}{4} \;\; \frac{8}{9}\\ 9 & \frac{1}{5} \;\; \frac{2}{9} \;\; \frac{2}{5} \;\; \frac{4}{9} \;\; \frac{3}{5} \;\; \frac{2}{3} \;\; \frac{4}{5} \;\; \frac{8}{9} \\ 10 &\frac{2}{11} \;\; \frac{1}{5} \;\; \frac{4}{11} \;\; \frac{2}{5} \;\; \frac{6}{11} \;\; \frac{3}{5} \;\; \frac{8}{11} \;\; \frac{4}{5} \;\; \frac{10}{11}\\ 11 & \frac{1}{6} \;\; \frac{2}{11} \;\; \frac{1}{3} \;\; \frac{4}{11} \;\; \frac{1}{2} \;\; \frac{6}{11} \;\; \frac{2}{3} \;\; \frac{8}{11} \;\; \frac{5}{6} \;\; \frac{10}{11}\\ 12 & \frac{2}{13} \;\; \frac{1}{6} \;\; \frac{4}{13} \;\; \frac{1}{3} \;\; \frac{6}{13} \;\; \frac{1}{2} \;\; \frac{8}{13} \;\; \frac{2}{3} \;\; \frac{10}{13} \;\; \frac{5}{6} \;\; \frac{12}{13} \end{array} I now rewrote this (by extending by 2 here and there) to get \begin{array}{c|c} k & \phi_k \\ \hline 2 & \frac{2}{3}\\ 3 & \frac{2}{4} \;\; \frac{2}{3}\\ 4 & \frac{2}{5} \;\; \frac{2}{4} \;\; \frac{4}{5}\\ 5 & \frac{2}{6} \;\; \frac{2}{5} \;\; \frac{4}{6} \;\; \frac{4}{5}\\ 6 & \frac{2}{7} \;\; \frac{2}{6} \;\; \frac{4}{7} \;\; \frac{4}{6} \;\; \frac{6}{7}\\ 7 & \frac{2}{8} \;\; \frac{2}{7} \;\; \frac{4}{8} \;\; \frac{4}{7} \;\; \frac{6}{8} \;\; \frac{6}{7}\\ 8 & \frac{2}{9} \;\; \frac{2}{8} \;\; \frac{4}{9} \;\; \frac{4}{8} \;\; \frac{6}{9} \;\; \frac{6}{8} \;\; \frac{8}{9}\\ \vdots & \vdots \end{array} which clearly reveals the pattern given above. Here are the first 100 sets of solutions: And 500:

Is this conjecture on Fibonacci sums correct?

I have the following conjecture, need to know a proof just in case mine is wrong, or the conjecture itself is wrong. The sum of k distinct Fibonacci numbers can be written in at most k ways as the sum of another k distinct numbers from the sequence Proof: Take, say 4, Fibonacci numbers with distinct values: $$144+34+3+2$$ We can see that we must maintain the distinctness and number of the Fibonacci numbers. So when we split the numbers; $$[89+55]+[13+21]+3+2$$ It is immediately apparent that if some numbers are split into smaller Fibonacci numbers, others must be merged to keep only 4 numbers. Thus, 3+2 becomes 5, and either 144 or 34 kept as-is. Thus, $$144+34+3+2=89+55+34+5=144+21+13+5$$ I know it's a rudimentary proof, and k ways of writing the same sum is probably a wrong upper bound, but at least it works for now. Please do let me know what's wrong. Thanks.

If $|G_1|=|G_2|<\infty$ and $|G_1'|<|G_2'|$, then $|Z(G_1)|\geq |Z(G_2)|$? where G' is the commutator subgroup of G.

We know that G' characterization how ``abelian'' of a group because we have a theorem: if $G'=\{e\}$, then G is abelian. I have a conjecture. If there are two finite groups G_1 and G_2, $|G_1|=|G_2|$ and $|G_1'|< |G_2'|$, where G' is the commutator subgroup of G, does it imply that $|Z(G_1)|\geq |Z(G_2)|$? Or find a counterexample, is there an example satisfing $|G_1|=|G_2|<\infty$, $|G_1'|< |G_2'|$ and $|Z(G_1)|< |Z(G_2)|$? This conjecture is true for $|G|\leq 30$ by verify manually myself and this website. Remarks There is a similar theorem: if $\text{inn }G=\{e\}$, then G is abelian, where $\text{inn }G$ is the group of inner automorphism on G. If there are two finite groups G_1 and G_2, $|G_1|=|G_2|$ and $|\text{inn }G_1|< |\text{inn }G_2|$, which imply that $|Z(G_1)|> |Z(G_2)|$ because $G/Z(G)\cong \text{inn }G$.

Are there infinitely many primes in any sequence determined by a k that is not a Sierpinski number?

Consider the sequence of numbers ranging over n of the form $k\cdot a^n + 1$ for a fixed, odd natural number k. The number k is considered a Sierpinski number if the sequence determined by that k contains no primes. One way to show that such a k is a Sierpinski number is to find a covering system of congruences for the sequence proving there are no primes in the sequence. The way to show that such a k is not a Sierpinski number is to find one prime among the numbers in the sequence. For those sequences where a prime has been found, that is, k is not a Sierpinski number, is it known whether there could be infinitely many primes in that sequence? If only a finite number of primes are expected to be in the sequence, then a covering system of congruences might work after a certain n to show that the rest of the sequence contains only composite numbers. Sierpinski showed that there are an infinite number of k whose sequences contain no primes. My conjecture is that there can be at most a finite number of primes for any k, but I wonder if this has not already been resolved by someone or if someone has already made the conjecture.

$\sum\limits_i a_i^2\sum\limits_i b_i^2+\left(\sum\limits_ia_i b_i\right)^2\geq \sqrt{\sum\limits_i a_i^4\sum\limits_i b_i^4}+\sum\limits_ia_i^2b_i^2$

I have no idea about how to prove (or disprove) the following inequality: $$ \left(\sum_{i=1}^n a_i^2\right)\left(\sum_{i=1}^n b_i^2\right)+\left(\sum_{i=1}^na_i b_i\right)^2\geq \sqrt{\left(\sum_{i=1}^n a_i^4\right)\left(\sum_{i=1}^n b_i^4\right)}+\sum_{i=1}^na_i^2b_i^2,\quad a_i,b_i\in\mathbb{R}, \ n>1. $$ I ran some numerical simulations and no counterexample showed up yet. Note 1. The inequality holds true for $n=2$, as shown here. Note 2. This conjecture was formulated by Fedor Petrov in an attempt to provide a solution to a particular case of this question. EDIT. The inequality has been finally proved here.

Is the following inequality involving the sum-of-divisors and Euler totient functions true?

First Question Is the following inequality involving the sum-of-divisors σ and Euler totient ϕ functions true? $$\frac{\sigma(N)}{N} \leq \frac{N}{\phi(N)}$$ Second Question When N satisfies $\sigma(N) = 2N - p$ for some $p > 1$, we say that N is p-deficient and we know that $$\frac{2N}{3N - \sigma(N)} < \frac{\sigma(N)}{N}.$$ Assuming the previous inequality is correct, this gives the upper bound $$\frac{\phi(N)}{N} < \frac{3}{2} - \frac{\sigma(N)}{N}.$$ (Consider $N = 2^r$ where $r \geq 1$. (Note that N is deficient.) Then $$\frac{\sigma(N)}{N} = \frac{\sigma(2^r)}{2^r} \geq \frac{\sigma(2)}{2} = \frac{3}{2}.$$ This agrees with the fact that $p = 2N - \sigma(N) = 2(2^r) - \sigma(2^r) = 1$.) These considerations bring me to my next question: Is there a nice lower bound for $\phi(N)/N$ that will allow us to rule out many, if not most, deficient values for N?

Uniqueness or non uniqueness of a pair of natural numbers

Let $1<m<n$ be two natural numbers. Let us call (m,n) a math.se pair if the prime factors of m are the same as those of n and the prime factors of $m+1$ are the same as those of $n+1$, e.g. $(2,8)$. For every $s\geq 2$, the pair $((2^s-2),2^s(2^s-2))$ is such a pair (for $s=2$ we have the previous pair). The question I asked myself was: are there other math.se pairs, i.e., math.se pairs not of the form $((2^s-2),2^s(2^s-2))$? So, I made a

fortran program that verifies if (i,j) is a math.se pair for $1<i<j$ and for $1<i\leq m$ and $m<j\leq n$ where m and n are input values, but the only different math.se pair that I (actually, it was the computer) found is $(75,1215)$ (we have that $75=3\cdot5^2$, $1215=3^5\cdot 5$, $76=2^2\cdot19$ and $1216=2^6\cdot19$). The problem is that the greater i or j is, the greater is the time the computer takes. Now I wonder if that $(75,1215)$ is the only math.se pair not of the form $((2^s-2),2^s(2^s-2))$. If there are others, are there infinitely many of them? If yes, can we list them all? If you look carefully, you'll see that $(a_s+1)^2=b_s+1$, where $a_s=2^s-2$ and $b_s=2^s(2^s-2)$. With this in mind, I tried to obtain a math.se pair (a,b) that satisfies $(a+1)^3=b+1$. In this case, we need to find a number b, such that $b=a^3+3a^2+3a$ and such that b and a have the same prime factors. But even in this case I don't know how to show if there is or if there isn't such a math.se pair.

A conjecture about traces of projections

Let M_n denote the space of all $n\times n$ complex matrices. Define $\tau:M_n\rightarrow \mathbb{C}$ by $$\tau(X)=\frac{1}{n}\sum_{i=1}^n x_{ii},$$ where of course $X=[x_{ij}]\in M_n$. Recall that a matrix $P\in M_n$ is called an "orthogonal projection" if $P=P^*=P^2$. Let A, B, C be orthogonal projections in M_n and define two quantities - $$x=\frac{1}{3}\tau(A+B+C)$$ and $$y=\frac{1}{3}\tau(AB+BC+CA).$$ It is easy to see that for any orthogonal projections $A,B,C\in M_n$ the value of x lies in $[0,1]$. I want to investigate the case when $x\in [\frac{1}{3},\frac{1}{2}]$. My goal is to compute the infimum of y under this constrain on x. My observation is that the minimum value of y is $\frac{3x-1}{4}$ when $x\in [\frac{1}{3},\frac{1}{2}]$ and for all $n\in \mathbb{N}$. However I am unable to prove this and I wondered if people here may be able to see why this might hold, or provide a counterexample to this conjecture.

How close are we to knowing the rate of convergence to 0 of $\prod_{p\le x}(1-1/p)^{-1}-e^\gamma\log x $?

This is a question related to an earlier one of mine, which I may answer myself eventually, as I have learnt more about the topic. Despite what one can read on the MathWorld page about Mertens' third theorem, in 2009 Diamond and Pintz showed$$\underset{p\ \text{prime}}{\prod_{p\le x}}\left(1-\frac1p\right)^{-1}-e^\gamma\log x=\Omega_{\pm}\left(\frac{\log\log\log x}{\sqrt{x}}\right);$$on the other hand, by a theorem of Dusart, for all $x\ge2973$ $$\left\lvert\prod_{p\le x}\left(1-\frac1p\right)^{-1}-e^\gamma\log x\right\rvert <\frac{0.2}{\log x}.$$ In the end of 2014, using a probabilistic argument, Lamzouri conjectured $$\left\lvert\prod_{p\le x}\left(1-\frac1p\right)^{-1}-e^\gamma\log x\right\rvert \sim \frac{e^\gamma}{2\pi}\frac{(\log\log\log x)^2}{\sqrt{x}}.$$ Has it been established that$$-\infty<\liminf_{x\to\infty}\frac{\sqrt{x}}{(\log\log\log x)^2}\left(\prod_{p\le x}\left(1-\frac1p\right)^{-1}-e^\gamma\log x\right)<0 \ ?$$I googled quite a lot, but I could find nothing. Has there been no progress yet?

conjectured general continued fraction for the quotient of gamma functions

Given complex numbers $a=x+iy$, $b=m+in$ and a gamma function $\Gamma(z)$ with $x\gt0$ and $m\gt0$, it is conjectured that the following general continued fraction which is symmetric on a and b is true $$\frac{\displaystyle\Gamma\left(\frac{a+3b}{4(a+b)}\right)\Gamma\left(\frac{3a+b}{4(a+b)}\right)}{\displaystyle\Gamma\left(\frac{3a+5b}{4(a+b)}\right)\Gamma\left(\frac{5a+3b}{4(a+b)}\right)}=\cfrac{4(a+b)}{a+b+\cfrac{(2a)(2b)}{3(a+b)+\cfrac{(3a+b)(a+3b)}{5(a+b)+\cfrac{(4a+2b)(2a+4b)}{7(a+b)+\ddots}}}}}\tag{1}$$ And can be further generalised to $$\frac{1}{\sqrt{c}}\tan\left(\frac{b-a}{b+a}\tan^{-1}\left(\frac{\sqrt{c}}{d}\right)\right)=\cfrac{(b-a)}{d(a+b)+\cfrac{c(2a)(2b)}{3d(a+b)+\cfrac{c(3a+b)(a+3b)}{5d(a+b)+\cfrac{c(4a+2b)(2a+4b)}{7d(a+b)+\ddots}}}}\tag{2}$$ Corollaries: (i) Specializing to $a=1/2$ and $b=2z/n+1/2$,we obtain the continued fraction for $\tan\left(\frac{z\pi}{4z+2n}\right)$ found in this post after applying the functional equation of the gamma function (ii) and specializing further to $a=-1/2$ and $b=2z/n+3/2$,we obtain immediately the continued fraction for $\cot\left(\frac{z\pi}{4z+2n}\right)$ found here after applying the functional equation of the gamma function.This continued fraction was proved by @GEdgar. (iii) letting $2a=m-n$ and $2b=m+n$,we find $$\displaystyle\tan\left(\frac{\pi n}{4m}\right)=\cfrac{n}{m+\cfrac{m^2-n^2}{3m+\cfrac{4m^2-n^2}{5m+\cfrac{9m^2-n^2}{7m+\cfrac{16m^2-n^2}{9m+\ddots}}}}}$$ From which we obtain its hyperbolic companion $$\displaystyle\tanh\left(\frac{\pi n}{4m}\right)=\cfrac{n}{m+\cfrac{m^2+n^2}{3m+\cfrac{4m^2+n^2}{5m+\cfrac{9m^2+n^2}{7m+\cfrac{16m^2+n^2}{9m+\ddots}}}}}$$ (iv)and if $2a=-n$ and $2b=2m+n$,then it follows that $$\displaystyle\tan\left(\frac{\pi(m+n)}{4m}\right)=\frac{1+\tan\Big(\frac{\pi n}{4m}\Big)}{1-\tan\Big(\frac{\pi n}{4m}\Big)}=\cfrac{m+n}{m+\cfrac{(-n)(2m+n)}{3m+\cfrac{(m-n)(3m+n)}{5m+\cfrac{(2m-n)(4m+n)}{7m+\cfrac{(3m-n)(5m+n)}{9m+\ddots}}}}}$$ Q: Is the conjectured general continued fraction true (for all complex numbers a,b with $x\gt0$ and $m\gt0$)?

Endowing module with algebra

Given a module M over a ring R, is it possible to endow M with an operation $M^{2} \to M$ that turns M to an algebra that is not the trivial $m n \equiv \mathbf{0}$ identically? So far I have that if M is a free module, i.e. it has a basis, then we can define a pointwise multiplication that non-trivially makes M an algebra. My first thought after this was to consider M as a direct sum $R \oplus N$ for some submodule $N \subseteq M$, and define it by $(r, n)(r', n') = (r r', 0)$, but even this (if my module can be written as the direct sum as earlier supposed) feels kinda trivial. So the next question: can any module M be endowed with multiplication such that N is a nontrivial subalgebra for every nontrivial submodule $N \subseteq M$? I'm quite at a loss on how to show it. Thanks.

Factoring the factorials

Just for the fun of it, I've started factoring $n!$ into its prime divisors, and this is what I got for $2\leq n\leq20$: $$\begin{align} 2! &= 2^\color{red}{1} &S_e=1\\ 3! &= 2^\color{red}{1} \cdot 3^\color{red}{1} &S_e=2\\ 4! &= 2^3 \cdot 3^\color{red}{1} &S_e=4\\ 5! &= 2^3 \cdot 3^\color{red}{1} \cdot 5^\color{red}{1} &S_e=5\\ 6! &= 2^4 \cdot 3^2 \cdot 5^\color{red}{1} &S_e=7\\ 7! &= 2^4 \cdot 3^5 \cdot 5^\color{red}{1} \cdot 7^\color{red}{1} &S_e=8\\ 8! &= 2^7 \cdot 3^2 \cdot 5^\color{red}{1} \cdot 7^\color{red}{1} &S_e=11\\ 9! &= 2^7 \cdot 3^4 \cdot 5^\color{red}{1} \cdot 7^\color{red}{1} &S_e=13\\ 10! &= 2^8 \cdot 3^4 \cdot 5^2 \cdot 7^\color{red}{1} &S_e=15\\ 11! &= 2^8 \cdot 3^4 \cdot 5^2 \cdot 7^\color{red}{1} \cdot 11^\color{red}{1} &S_e=16\\ 12! &= 2^{10} \cdot 3^5 \cdot 5^2 \cdot 7^\color{red}{1} \cdot 11^\color{red}{1} &S_e=19\\ 13! &= 2^{10} \cdot 3^5 \cdot 5^2 \cdot 7^\color{red}{1} \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} &S_e=20\\ 14! &= 2^{11} \cdot 3^6 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} &S_e=22\\ 15! &= 2^{11} \cdot 3^6 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} &S_e=24\\ 16! &= 2^{15} \cdot 3^6 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} &S_e=28\\ 17! &= 2^{15} \cdot 3^6 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} \cdot 17^\color{red}{1} &S_e=29\\ 18! &= 2^{16} \cdot 3^8 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} \cdot 17^\color{red}{1} &S_e=32\\ 19! &= 2^{16} \cdot 3^8 \cdot 5^3 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} \cdot 17^\color{red}{1} \cdot 19^\color{red}{1} &S_e=33\\ 20! &= 2^{18} \cdot 3^8 \cdot 5^4 \cdot 7^2 \cdot 11^\color{red}{1} \cdot 13^\color{red}{1} \cdot 17^\color{red}{1} \cdot 19^\color{red}{1} &S_e=36\\ \end{align}$$ where S_e is the sum of the exponents. There are lots of interesting patterns to chase here, but I've focused on the prime factors with exponent 1 (highlighted). My conjecture is, In the sequence above, prime factor p^1 will appear p times starting from $p!$. Or, otherwise stated, $\forall k = 2p-1$, $k!$ is the last term of the sequence $\{a_n\}=n!$ to have p^1 as one of its prime factors. [I could not find any reasonable pattern concerning p^2.] This might be some well-known fact, but as someone who hasn't seen prime factorization since elementary school I was wondering how this could be proven (or whether it is even right, although it looks like it is).

Conjecture about odd primes

For each odd prime p there exist $n\in\mathbb{N}$ such that $p\equiv n^2 \text{ (mod }\varphi(n^2))$, where φ is Euler's totient function. I'm developing my Forth based computational system Zet to be used for testing conjectures and it seems that it generate conjectures as well... What I have tried is to test the modular condition for squares of all integers less than n. All odd primes less than n are represented then. It's not so that all odd number is represented - which seems to be the case if dropping the squaring: $p\equiv n \text{ (mod }\varphi(n))$ - instead the most of the numbers represented are primes.

A conjecture about primes: if a,b are coprime and not both odd, is $A(a,b,m)$ finite for some m?

Let p_n be the nth prime and define $p_n^{(m)}$ by $p_n^{(1)}=p_n$ and $p_n^{(m+1)}=p_{p_n^{(m)}}$: $p_n^{(2)}=p_{p_n}$, $\;p_n^{(3)}=p_{p_{p_n}}$ and so far... For some coprime numbers a,b, not both odd, do there exist a number $m\in \mathbb Z_+$ such that $A(a,b,m)=\{ap_n^{(m)}+b\in\mathbb P|n\in\mathbb Z_+\}$ is finite? $\mathbb P$ is the set of primes. I have done some tests and there is no sign of finiteness. Conjecture: If a and b are coprime and $a+b$ is odd, then $A(a,b,m)$ is infinite for all $m\in\mathbb Z_+$. One consequence of the conjecture, which I don't expect to be proved, is that any even gap just not only exists but exists infinitely, not only for primes, but also for the case when one of the primes is of the form $p_n^{(m)}$ any m. So perhaps there is a possibility of counterexamples? See also this paper.

A stronger form of Rolle's Theorem in the direction of number of roots of $f'(x)$

Today I read an interesting generalization of the Rolle's Theorem for Polynomials in $E. 28$ of E. J. Barbeau's book on Polynomials. It says that if a, b are two consecutive zeroes of polynomial $P(x)$ then the number of roots $P'(x)$ (counting multiplicities) in (a, b) is odd in number. I saw the proof and all. Now, this made me conjecture a similar thing for any differentiable function, given consecutive roots exist (roots are countable). ALso, I had to assume that the number of roots of $f'(x)$ in (a, b) is finite in number. Also, I don't know if this makes sense, but I also defined multiplicity of roots for $f(x)$ as if $f(a)=f'(a)= \cdots = f^{(n)}(a)=0$ and $f^{(n+1)} \neq 0$, then I say that multiplicity of a is n and I count it as n roots. My conjecture is that the number of roots of $f'(x)$ (counting orders) stictly between any two consecutive roots of f is odd in number. Also, I think I have proved it given the assumptions. Because clearly the extremums of $f(x)$ between a and b are odd in number and any point critical point in (a, b) that is not an extremum will be a root with even multiplicity by nth derivative test which I can prove. So, the conjecture holds. Now, my main questions are, is there a better form of the above conjecture? Also, are any of my assumptions on the countability and infinitude of roots "unecessary"? Are there any analogous results when the roots of $f'(x)$ are infinitude? Please throw light. Now my question is not very specific or may its asking for too many things, so any related results or links will also be immensely appreciated. Also I am in high school and don't much analysis analysis (i know uptil spivak calculus). UPDATE: Since my conjecture (with the assumptions stated seems true) and we are trying to find and analogous extension of it for the case of infinitely many derivatives, I thought we must try to extend the notion of cardinality of a set with odd number of elements to sets with infinitely many elements. Here is my proposed extension: Call the cardinality of a set S with infinitely many elements, odd iff we cannot cannot partition S into A and B such that there exists a bijection from A to B. When the cardinality is finite, then the above definition is clearly true by definition. So, does the above extension make sense (even when the set is countable)? Now with the above definition can we say that the number of roots of $f'(x)$ in (a, b) odd? (at least when the roots are countably infinite?)

Conjecture about Rabin-Miller pseudo prime test

I tested the Rabin-Miller pseudo prime algorithm using a single test value and found that the number of false calls depends on the size of the number to test, reducing to a (conjectured) negligible probability of error for very large numbers. A number is randomly chosen to be tested. If the number is $0,1,2,3$ or even the correct result is returned. If the number is odd and >3 the Rabin-Miller algorithm specified below is used. The result is compared with table values. This algorithm use a random number a for the test. It would never miss a prime but occasionally report a composite to be a prime. If the test is erroneous an error is returned. I used the method at oeis A014233 where a method for exact testing of primes using multiple Rabin-Miller tests is described, together with squeezed prime tables, to assess the truth of primality. For each b I ran the test $10,000,000$ times with pseudo random numbers less than 2^b and then got the following number of errors e: e b f 78144 8 78125 61425 9 55243 43642 10 39063 32688 11 27621 22201 12 19531 15190 13 13811 10789 14 9766 7176 15 6905 4814 16 4883 3227 17 3453 2122 18 2441 1422 19 1726 926 20 1221 574 21 863 400 22 610 247 23 432 194 24 305 112 25 216 65 26 153 46 27 108 24 28 76 21 29 54 11 30 38 9 31 27 2 32 19 4 33 13 4 34 10 0 35 7 2 36 5 0 37 3 0 38 2 0 39 2 0 40 1 0 41 1 The f-column is the function $f(b)=1250000\cdot 2^{-\frac{b}{2}}$. The algorithm used is: To test an odd number n, write $n=2^r\cdot s+1$, where s is odd. Given a random number a such that $1<a<n$, if 1. $a^s\equiv 1(\text{mod}\; n)$ or 2. it exists an integer j: $0\le j<r$ with $a^{2^j\cdot s}\equiv -1(\text{mod}\; n)$ then n is pseudo prime. The conjecture is: For b big enough $\text{e}<1250000\cdot 2^{-\frac{b}{2}}$. And specially, $\text{e}\sim 2^{-\frac{b}{2}}$. I intend to use the algorithm for testing big integers and it seems like just one test is enough for $b>256$ since $f(256)=\frac{1}{272225893536750770770699685945414}\,$, which is supposed to be the probability for an error within 10,000,000 random primary tests. For $b<<256$ one can use multiple tests or an exact algorithm. But how to prove the conjecture or at least make it resonable? I will also reward an indepentent computer test, that support or not support my own computer test. I made a test with double check of Rabin-Miller and made a diagram:

Integer Partition by Counting Repetition : Conjecture ??

I would like to find informations regarding this way of doing Integer Partitions or this conjecture, Suppose you have all the ordered partitions of 5: 5 4 1 3 2 2 2 1 3 1 1 2 1 1 1 1 1 1 1 1 Then extend those partitions to 5 digits by adding 0: 5 0 0 0 0 4 1 0 0 0 3 2 0 0 0 2 2 1 0 0 3 1 1 0 0 2 1 1 1 0 1 1 1 1 1 And finaly for each extended partitions, count the digit repetitions, like this: 5 0 0 0 0 -> 1 4 4 1 0 0 0 -> 1 1 3 3 2 0 0 0 -> 1 1 3 2 2 1 0 0 -> 2 1 2 3

1 1 0 0 -> 1 2 2 2 1 1 1 0 -> 1 3 1 1 1 1 1 1 -> 5 And you can repeat ! 5 0 0 0 0 -> 1 4 -> 1 4 0 0 0 -> 1 1 3 -> 1 1 3 0 0 -> 2 1 2 -> 2 1 2 0 0 -> 1 1 1 2 -> .. 4 1 0 0 0 -> 1 1 3 -> 1 1 3 0 0 -> 2 1 2 -> 2 1 2 0 0 -> 1 1 1 2 -> 1 1 1 2 0 -> 3 1 1 3 2 0 0 0 -> 1 1 3 -> 1 1 3 0 0 -> 2 1 2 -> 2 1 2 0 0 -> 1 1 1 2 -> 1 1 1 2 0 -> 3 1 1 2 2 1 0 0 -> 2 1 2 -> 2 1 2 0 0 -> 1 1 1 2 -> 1 1 1 2 0 -> 3 1 1 -> 3 1 1 0 0 -> 1 2 2 3 1 1 0 0 -> 1 2 2 -> 1 2 2 0 0 -> 1 2 2 -> 1 2 2 0 0 2 1 1 1 0 -> 1 3 1 -> 1 3 1 0 0 -> 1 1 1 2 -> .... -> 1 2 2 1 1 1 1 1 -> 5 -> 5 0 0 0 0 -> 1 4 -> 1 4 0 0 0 -> 1 1 3 -> ... -> 1 2 2 All of them finish in 1 2 2! I want informations, documentations Thanks a lot!

Conflicting conjectures

I feel like when two conjectures are inconsistent with one another, it's a clear sign of our misunderstanding of deeper mathematics. I was wondering if anyone knew of a comprehensive list of conjectures that contradict other conjectures.

Seeking proof to a Hyperbolic polygon conjecture

In the course of writing a(n Honours) thesis, I'm searching for a proof to a conjecture that appears very likely to be true. Many results will rely upon it. My own attempts to prove it have been unfruitful, and at this point I'd be happy to settle for a reference to something in the literature. Here's the conjecture: Let $O,V_1, \dots V_{n-2} ,f$ be an $n-$pointed convex polygon in H^2. Given all outer angles (those between adjacent edges of the polygon), and angles $\angle V_n O V_m$ and $\angle V_{n-2} O f$, the entire polygon is uniquely determined up to isometry. Pictorial statement of the conjecture: Given all outer angles of an $n-$pointed convex polygon, and all α_i, the full geometry of the shape is determined up to isometry.

There are at least two solutions such that $2p_n=p_a+p_b$ (p being prime)

I've stumbled across this playing around and summing primes at random during a boring lecture. Is this a known conjecture? Can it be proven? My conjecture: There exists at least one non trivial solution such that $2p_n = p_a + p_b$ (the trivial being obviously $a=b=n$) for $n > 2$. Tested by starting at the trivial $2p_n = p_n + p_n$ then incremented the right as I decremented the left until both were prime again or I've ran below 2 with the left number. The second condition never occurred though, and I've tested for the first 1000 primes by writing a simple program. It fascinated me for the fact that this would mean that $p_b = 2p_n - p_a$ where $b > n > a$ so by knowing primes up to the nth you would have enough information to evaluate the $(n + 1)$-th?

Closed form and limit of the integral of a rational function

While trying to answer this question, I wondered whether there could be a way to: (A) Find the closed form of the generalization of integrals I and J, that is $$I_n=\int_{-\infty}^{+\infty}\frac{dx}{x^{4n}+x^{2n}+1}$$ (B) Prove my own conjecture that $$\lim_{n \to \infty}I_n = 2$$ Is there a clean way to do these? EDIT: I have managed to find a closed form for the poles of the integrand that lie in the upper half-plane, which would be the ones lying within the usual semicircular contour: $$\omega^+_n(j)=\exp\left(i\frac{\pi}{4n}\big(2j-1-(-1)^n\big)\right) \qquad 1 \leq j \leq 2n, \quad j \in \mathbb{N}$$ My integral would become $$\def\res{\mathop{\text{Res}}} \begin{align} \oint_\Gamma \frac{dz}{z^{4n}+z^{2n}+1}&=\lim_{R\to\infty} \int_{-R}^{+R}\frac{dx}{x^{4n}+x^{2n}+1}+\lim_{R\to\infty}iR\int_{0}^{\pi}\frac{e^{i\theta}d\theta}{R^{4n}e^{i\theta4n}+R^{2n}e^{i\theta2n}+1} \\ &=2\pi i \sum_{j=1}^{2n} \res_{z=\omega^+_n(j)} \left(\frac{1}{z^{4n}+z^{2n}+1}\right) \end{align}$$ The limit of the integral in θ is 0, as one would expect, so my question reduces to: Is there a way to express $$\sum_{j=1}^{2n}\res_{z=\omega^+_n(j)} \left(\frac{1}{z^{4n}+z^{2n}+1}\right)$$ in terms of n and j? The answers to (A) and (B) above should follow from this in a relatively straightforward way.

Is the Fermat primality test secure enough for very big numbers?

The random variable X_m is the number of trials before $n\notin\mathbb P\wedge n\mid 2^{n-1}-1$ where n is an odd random integer $2^{m-1} < n < 2^m$. Computer simulations makes me believe that $\text E[\log X_m]=\frac{m}{6}$ and that $\operatorname{Var}[\log X_m]<1$. I'm looking for some kind of proof of this conjecture and would like to know how to compute or estimate $P(X_{1000}=1)$, given that the conjecture is true. The context is: how secure is the Fermat primality test with base 2 on numbers with 1000 binary bits? Compared with the probability of hardware errors? Well, perhaps the 10 in the logarithm doesn't flag for an exact $\frac{m}{6}$. The regression line is $\log N= 0.1666\cdot m+0.006$ which is interpreted as $N=10^{\frac{m}{6}}$ but might also be interpreted as $N=\pi^{\frac{m}{3}}$ within the marginals. $\overset{..}{\smile}$ 3251 simulations total so far. Some lower experiments $(m=10)$ has been removed, since lower intervalls gives more irregular results. In some intervalls there are no discrepancies. Also long time running results from $m=40$ is included, so the equation of the line of regression has changed a little. Diagram of the mean values of each m

Conjecture about primes and the factorial: for all primes $p>5$, must there exist a prime $q<p$ such that $q\equiv m!\pmod p$ for some $2<m<p$?

Below $0\notin\mathbb N$. Further corrected conjecture: For all prime numbers $p>5$ there exist a prime number $q<p$ such that $q\equiv m!\!\pmod p$, $2<m<p$. or Given a prime $p>5$ there exist a prime $q<p$ and $k,m\in\mathbb N$, $2<m<p$, such that $kp+q=m!$ I want help to prove the conjecture (which is tested for all $p<100,000,000$) or to find a counter-example. p=7 q=3 k=3 m=4 p=11 q=2 k=2 m=4 p=13 q=11 k=1 m=4 p=17 q=7 k=1 m=4 p=19 q=5 k=1 m=4 p=23 q=5 k=5 m=5 p=29 q=23 k=173 m=7 p=31 q=7 k=23 m=6 p=37 q=17 k=19 m=6 p=41 q=23 k=17 m=6 p=43 q=29 k=937 m=8 p=47 q=11 k=107 m=7 p=53 q=31 k=13 m=6 p=59 q=2 k=2 m=5 p=61 q=59 k=1 m=5 p=67 q=53 k=1 m=5 ... Up to the prime 1020361 For several reasons I have had major problems extracting my real observations. Also, the primes are not unique having this property, a lot of semiprimes, but not all, and occasionally some other numbers, also have it. It seems like less than one third of all natural numbers have it and there is a secondary conjecture: For all primes p there is a prime $q<p^2$ such that $q\equiv m!\pmod {p^2}$, $2<m<p^2$. tested for all $p<100,000,000$. There are strong reasons to believe that the conjecture is true. Suppose $0\equiv m!\!\pmod n$, then $0\equiv r!\!\pmod n$ for all $r>m$. And suppose $n=sp^t$, where p is the largest prime dividing n, $p\nmid s$ and $t>0$, then $0\equiv (pt)!\!\pmod n$. If p is a large prime there are a lot of nonzero solutions to $x\equiv m!\!\pmod p$ and the probability for one of those solutions to be a prime increase with p.

Conjecture concerning modular arithmetic

Below $0\notin\mathbb N$. I want a proof or a counter-example of the following (corrected) conjecture: Suppose p is the smallest prime dividing $n\in\mathbb N$ and suppose $kn+ap=m!$, where $ap<kn$, for some $a,k,m\in\mathbb N$, then there are $k^{\prime},a^{\prime}\in\mathbb N$ such that $k^{\prime}n+a^{\prime}p=(m+1)!$, where $a^{\prime}p<k^{\prime}n$. A more simple way to write the conjecture is (with some abuse of language): Suppose p is the smallest prime dividing $n\in\mathbb N$ and suppose $p|(m!\pmod n)$, then $p|((m+1)!\pmod n)$

What are the mathematical consequences if 10 is proved to be solitary?

Let $\sigma(x) = \sigma_{1}(x)$ denote the sum of the divisors of x, and let $$I(x) = \dfrac{\sigma(x)}{x}$$ be the abundancy index of x. For example, $$\sigma(10) = 1 + 2 + 5 + 10 = 18$$ so that $$I(10) = \dfrac{\sigma(10}{10} = \dfrac{18}{10} = \dfrac{9}{5}.$$ Consider the equation $$I(x) = I(a)$$ where a is fixed. If $x \neq a$, then x is said to be a friend of a. We will then call x and a as friendly numbers. On the other hand, if $x = a$ whenever $$I(x) = I(a),$$ then a is called a solitary number. In this paper by Ward, necessary conditions for the existence of a friend of 10 is derived. It is conjectured that 10 is in fact solitary, although a proof appears to be very difficult. My question in the present post is as follows: What would be the mathematical consequences, if any, of proving that 10 is solitary?

Graph Laplacian rank-one update

Can anyone help me prove/disprove this conjecture? Let G be an undirected nonnegative weighted connected graph with n nodes and Laplacian matrix L. Also, let $0 = \lambda_1 < \lambda_2 \leq \dots\leq \lambda_n$ be eigenvalues of the Laplacian matrix L and assume that $\max(d_i)<1$, where d_i is the degree of i^th node. If $\lambda_i>1$ for some $2\leq i \leq n$, there exists an edge e such that increasing weight of e while having maximum degree less than one, does not increase number of eigenvalues larger than one. Here $d_i = \sum_i a_{ij}$ where a_{ij} is the ij^th component of the adjacency matrix of the graph.

Primes in the binomial transform of $ [1, 1, 2, 1, -1, 1, -1, 1, -1, 1, -1, 1, -1, ...]$.

This question is related to this sequence A139482. A commentator gives the following formula for a_m $$a_m = {3m^2-9m+10 \above 1.5pt 2}$$ I have that you should consider the sequence $b_n =3n+2$ and arrange the terms as follows: $$B_3 = \begin{matrix} &&&&&65&\ldots \\ &&&&47&62&\ldots \\ &&&32&44&59&\ldots \\ &&20&29&41&56&\ldots \\ &11&17&26&38&53&\ldots \\ 5&8&14&23&35&50&\ldots \end{matrix}$$ Then a_m appears to be the the sequence on the uppermost slope of B_3 for $m>2$. In particular a_m can be written as b_n for some suitable n. Dirichlet tells us there are infinitely many primes in B_3. The obvious question is are there infinitely many primes on the uppermost slope? If that is too much to ask can we show that every column or row of B_3 has at least one prime number? Update: I believe I have the differences of consecutive terms on the uppermost slope: $a_{m+1}-a_m=3(m+1)$. So that $a_{m+1} = 3(m+1)+a_m$. I also have that $(3,a_m) =1$ for every m. Would not Dirichlet's theorem tell us there are infinitely many primes of the form $3(m+1)+a_m$? <--- The answer to this question is NO!

Combining a working hypothesis for odd perfect numbers with an inequality for logarithms

Euler's theorem for odd perfect numbers states that if there exists and odd perfect number, that is an odd positive integer n satisfying $\sigma(n)=2n$, where $\sigma(m)=\sum_{d\mid m}d$ denotes the sum of divisor function, then this integer has the form $$n=p^{4\lambda+1}\cdot M^2$$ where the prime $p\equiv 1\text{ mod }4}$ and $\gcd(p,M)=1$. We assume the factorization $$n=p^{4\lambda+1}\prod_{\substack{q\text{ prime} \\ q\mid M}}q^{2e_q}$$ then it known the following Fact. Using Euler's theorem for odd perfect numbers, the condition to be perfect is written as $$2\cdot p^{4\lambda+1}\prod_{\substack{q\text{ prime} \\ q\mid M}}q^{2e_q}=\frac{p^{4\lambda+2-1}}{p-1}\prod_{\substack{q\text{ prime} \\ q\mid M}}\frac{q^{2e_q+1}-1}{q-1},$$ since the sum of divisor function is multiplicative. I've used the Lemma 7.9 from page 73 from Krizek, Luca and Somer, 17 Lectures on Fermat Numbers From Number Theory to Geometry Springer CMS (2001) (you can see this page as a Google Book, type here in Google Books the words: 17 lectures on fermat numbers lemma 7.9) with the specialization $y=q^{2e_q+1}-1$ and $x=p-1$ on assumption of the following Hypothesis A. For all prime $q\mid M$ $$p<q^{2e_q+1}-1$$ holds. I don't know if the following simple calculations were interesting. My purpose was do calculations and ask you Question. It is possible discard from the literature previous Hypothesis A as true? What other different hypothesis could be interesting to work from my approach? I am asking with my first question, if my hypothesis to work was absurd, and with the second question what hypotheis can I work with following calculations. I hope heuristics, that you cite the literature or mathematical reasonings. Thanks in advance. My approach was take the sum over all prime $q\mid M$ from the result of the specialization of cited Lemma 7.9, to show $$\frac{\log(p-1)}{\log p}\sum_{q\mid M}\log q^{2e_q+1}<\sum_{q\mid M}\log (q^{2e_q+1}-1),$$ and secondly take logarithms in Fact to combine showing that Claim. On assumption of Hypothesis A one has $$\log(2p^{4\lambda+1})+\sum_{q\mid M}\log q^{2e_q}>\log\frac{p^{4\lambda+2}-1}{p-1}+\frac{\log(p-1)}{\log p}\sum_{q\mid M}\log q^{2e_q+1}-\sum_{q\mid M}\log(q-1).$$ I am not saying that previous claim be interesting.

Does this category have a name? (Relations as objects and relation between relations as morphisms)

Given two relations $R\subseteq A\times B$ and $R'\subseteq A'\times B'$. Is it known/used that every relation $r\subseteq R\times R'$ can be characterized by two relations $\alpha\subseteq A\times A'$ and $\beta\subseteq B\times B'$ so that $((a,b),(a',b'))\in r \iff \Big((a,a')\in\alpha\wedge (b,b')\in\beta\wedge (a,b)\in R\implies (a',b')\in R'\Big)$ and if $R''\subseteq A''\times B''$, $\,r'\subseteq R'\times R''$, where r' is characterized by $\alpha'\subseteq A'\times A''$ and $\beta'\subseteq B'\times B''$, then the composition $r'\circ r$ is characterized by the relations $\alpha'\circ\alpha\subseteq A\times A''$ and $\beta'\circ\beta\subseteq B\times B''$? (Where $\circ$ denote the composition of relations). $\;$In diagram form: $\require{AMScd}$ \begin{CD} A@>\alpha>>A'@>\alpha'>>A''@. A@>\alpha'\circ\alpha>>A''\\ @VRVV r @VVR' V r'@VVR''V \quad\implies\quad @VRVV r'\circ r @VVR''V\\ B@>>\beta>B'@>>\beta'>B'' @. B@>>\beta'\circ\beta>B'' \end{CD} Does this category of relations as objects and relation between relations as morphisms have a name? The reason for my interest in this category: Suppose $A=B\times B$ and that $R\subseteq A\times B$ is the composition in a magma. Then the functions among the morphisms between two such objects defines magma morphisms $B\to B'$. Suppose $B=\mathcal P(A)$ and that $R\subseteq A\times B$ is the relation $(a,S)\in R\iff a\in\overline{S}$ for some topology on A. Then the functions among the morphisms between two such objects define continuous functions $A\to A'$. Edit: The category of relations as objects and pairs of relations defined by some α,β (as above) as morphisms, is a subcategory of the category of relations as objects and relations of relations as morphisms. Very few relations between relations can be defined with two relations α,β, but those relations which can seems to be an interesting category.

Even natural numbers are sums of two primes with twins or of two primes without twins

I seems to be very few even numbers that can't be written as a sum of two primes with twins or as a sum of two primes without twins. That is, suppose that $\mathbb P'$ is the set of the primes not belonging to a twin and that $\mathbb P''$ is the set of the primes belonging to a twin, then all but a finite number of even natural numbers can be written as $2n=p'+q',\quad p',q'\in\mathbb P'$ or as $2n=p''+q'',\quad p'',q''\in\mathbb P''$, due to a conjecture. So far the only exceptions are $0,2,96,98$ of even numbers $<100,000,000$. I'm interested in counterexamples and references. Below the number of ways to write 1000 as sum of two twin primes is 3, and the number of ways to write 1000 as sum of two non twin primes is 10. 100 terms cardinality . cardinality . 1 2 ok 1000 terms cardinality . cardinality . 10 3 ok 10000 terms cardinality . cardinality . 63 10 ok 100000 terms cardinality . cardinality . 415 64 ok 1000000 terms cardinality . cardinality . 3455 167 ok 10000000 terms cardinality . cardinality . 27081 1259 ok 100000000 terms cardinality . cardinality . 210124 5854 ok I see now that it seems to be a conjecture for the case $2n=p'+q',\quad p',q'\in\mathbb P'$, but then with a larger number of small exceptions: {0,2,4,6,8,10,12,14,16,18,20,22,24,26,28,30,32,34,36,38,40,42,44,46,48,50,52,54,56,58,62,64,66,68,72,78,80,82,86,88,92,96,98,108,110,118,122,124,128,138,140,148,152,170,182,188,208,212,218,222,232,238,266,268,272,282,292,296,328,332,358,362,392,482,512,628}. The corresponding set of small exceptions in the case $2n=p''+q'',\quad p'',q''\in\mathbb P''$ is: {0,2,94,96,98,400,402,404,514,516,518,784,786,788,904,906,908,1114,1116,1118,1144,1146,1148,1264,1266,1268,1354,1356,1358,3244,3246,3248,4204,4206,4208}. And the intersection is {0,2,96,98}.

If $|G|=p^3q^2$ then $\Phi(G)$ is cyclic for primes $p\neq q$.

I have conjectured this result for the Frattini subgroup by doing some calculations in GAP. I think this is even true if $|G|=p_1^{i_1}\cdots p_n^{i_n}$ for $i_j\leq 3$ holds, but I would like to stick with this example first. I know the following: If $p\mid |G|$, then $p\mid |G/\Phi(G)|$, thus the order of $\Phi(G)$ is at most p^2q. Since $\Phi(G)$ is nilpotent, it must be abelian, too. That's why I think that it suffices to show this result for only abelian G (which is fairly easy), as considering all abelian groups with that order would lead to all possible abelian $\Phi(G)$. But I still need a valid argument for that. I also tried the assumption $\Phi(G)=C_p\times C_p$ or $\Phi(G)=C_p\times C_p\times C_q$ but I have not yet found a contradiction. I would be glad to see some ideas or approaches for this conjecture.

Any even $n> 10$ can be written as $n = pp'+p''$ for some primes p,p',p''

Conjecture: Any even integer $n>10$ can be written as $n=p\cdot p'+p''$, for some $p,p',p''\in\mathbb P$. Verified for all $n<1,000,000$. I first intended to post the weaker conjecture: $\mathbb P\subset\Big(\mathbb P\cdot\mathbb P+\mathbb P+1\Big)\cup\{2,3,5,11\}$.

Conjectured Compositeness Test for $E_n(b)=\frac{b^{2^n}+1}{2}$

How to prove that following conjecture is true? Definition Let $P_m(x)=2^{-m}\cdot \left(\left(x-\sqrt{x^2-4}\right)^{m}+\left(x+\sqrt{x^2-4}\right)^{m}\right)$, where m and x are nonnegative integers. Conjecture Let $E_n(b)=\Large\frac{b^{2^n}+1}{2}$ such that $n>1$, b is odd number greater than one . Let $S_i=P_b(S_{i-1})$ with $S_0=P_{b}(6)$, thus If $E_n(b)$ is prime, then $S_{2^n-1} \equiv 6\pmod{E_n(b)}$. I have checked this conjecture for all odd $b \in [3,1999] $ with $n \in [2,10]$. Searching for counterexample (PARI/GP) : CEGF(g1,g2)= { forstep(b=g1,g2,[2], for(n=2,10,my(s=Mod(2*polchebyshev(b,1,3),(b^2^n+1)/2)); for(i=1,2^n-1, s=2*polchebyshev(b,1,s/2)); if(!s==6 && isprime((b^2^n+1)/2),print("b=",b,"n=",n)))) } PARI/GP implementation of test . GFOdd(b,n)= { my(s=Mod(2*polchebyshev(b,1,3),(b^2^n+1)/2)); for(i=1,2^n-1,s=2*polchebyshev(b,1,s/2)); s==6 } Any hint would be greatly appreciated .

The relationship between the order of an element in a group and the order of its image

I am wondering if the following is true: Let G be a finite group, $g \in G$, and let $\phi : G \rightarrow H$ be a group homomorphism to another finite group H. Then $|g| = |\phi(g)| \cdot |k|$ for some element k in $\ker \phi$. To be specific, the element $k \in \ker \phi$ is taken to be $g^{|\phi(g)|}$. This clearly satisfies $\phi(g^{|\phi(g)|}) = \phi(g)^{|\phi(g)|} = e$. I came up with a possible proof of this statement, but I wanted to see if anyone had counter-examples or insights on this issue. The proof I had is to show that $|g|$ divides $|\phi(g) \cdot |k|$ and conversely, that $|\phi(g)|$ divides $\frac{|g|}{|k|}$, using the fact $|x|$ divides n iff $x^n = e$.

Integer solutions to $2^x+3^y=9^z+8^w+8^t$

currently in number theory is there a method to solve for integer solutions to equations like $2^x+3^y=9^z+8^w+8^t$? For example, $2^{13}+3^6=9^3+8^4+8^4$. (obtained using computer brute force) In general, is there a way to solve for ${A_1}^{x_1}+{A_2}^{x_2}+\ldots+{A_n}^{x_n}={B_1}^{y_1}+{B_2}^{y_2}+\ldots+{B_m}^{y_n}$ or is it out of scope of the current number theory methods? (A_i and B_i are the given numbers, want to solve for x_i and y_i) Sincere thanks for help!

About the distribution of Gaussian prime pairs

The primes in the ring of Gaussian integers $\mathbb Z[i]$ has a simple connection to the ordinary primes: either one of the components is zero and the other is a prime of type $4n+3$ or the norm $\|a+ib\|=a^2+b^2$ is a prime $a\ne 0\ne b$, that is a prime of the type $4n+1$. All $n\in\mathbb Z^+$ with $n=a^2+b^2$, e.g. all ordinary primes of the form $4n+1$, are composites in $\mathbb Z[i]$: $n=(a+ib)(a-ib)$. There is essentially one pair of Gaussian primes such that $|z_1-z_2|=1$, and that is $(1+i,2+i)$. If defining prime pairs in $\mathbb Z[i]$ with $|z_1-z_2|=2$, then it seems like for each integer $n>0$ there is a prime $n+im\in\mathbb Z[i]$ with a prime as a pair. Can this be proved? Verified for all $a+ib\in\mathbb Z[i]$ with $0<a,b\leq1000$. I'll elaborate. If $|z_1-z_2|=2$ one can assume e.g. that $\Re (z_1-z_2)=0$ and $|\Im (z_1-z_2)|=2$. Hence, the conjecture can be formulated as: For each $a\in\mathbb N^+$ it exists $b\in\mathbb Z$ such that $a+ib$ and $a+i(b+2)$ are Gaussian primes. Equivalent conjecture: $\forall n\in\mathbb N^+\exists m\in\mathbb Z: n^2+m^2,n^2+(m+2)^2\in\mathbb P$.

Counting even and odd numbers in the columns of a triangular arrangement of the integers

I write the positive numbers starting at 1 in a triangle:$$\mathbb{N}_\triangle = \begin{matrix} &&&&&21&\ldots \\ &&&&15&20&\ldots \\ &&&10&14&19&\ldots \\ &&6&9&13&18&\ldots \\ &3&5&8&12&17&\ldots \\ 1&2&4&7&11&16&\ldots \end{matrix}$$ I would like some help proving the following claim I denote the count of even numbers in column n of $\mathbb{N}_\triangle$ by $e(n)$. Then for $n>1$ $$e(n) = \Bigg\lfloor{n+2 \above 1.5pt 4}\Bigg\rfloor+\Bigg\lfloor{n+1 \above 1.5pt 4}\Bigg\rfloor$$ Note the n^{th}-column$ of $\mathbb{N}_\triangle$ has n integers so I can set $f(n)$ to count the number of odd integers in $\mathbb{N}_\triangle$ and $$f(n) = n-e(n)$$ It appears that $e(n)\in$ A004524 This is being driven by hunches and computer checks. $e(n)$ can be simplified but I think it is easier to remember it the way it is written.

V3-018662 | MSE-1889549

Counting multiple of 3 in a triangular arrangement of the integers.

I write :$$\mathbb{N}_\triangle = \begin{matrix} &&&&&21&\ldots \\ &&&&15&20&\ldots \\ &&&10&14&19&\ldots \\ &&6&9&13&18&\ldots \\ &3&5&8&12&17&\ldots \\ 1&2&4&7&11&16&\ldots \end{matrix}$$ Can we determine how many numbers in any given column of $\mathbb{N}_\triangle$ are divisible by 3. I need help proving the following claim: If $f_3(n)$ counts the numbers in the n^{th} column of $\mathbb{N}_\triangle$ that are divisible by 3 then $$f_3(n) =\Bigg\lfloor{n+2 \above 1.5pt 3}\Bigg\rfloor$$ For example $$f_3(6) = \Bigg\lfloor{6+2 \above 1.5pt 3}\Bigg\rfloor=\Bigg\lfloor{8 \above 1.5pt 3}\Bigg\rfloor=\Bigg\lfloor 2.66666\Bigg\rfloor =2$$ and surely there are 2 numbers in column six that are divisible by 3. I suspect there are no multiples of 3 on the base of the triangle since possibly $$\Bigg(3, 1+ {n(n-1) \above 1.5pt 2}\Bigg)=1$$ In fact if $(3,T_n)=1$ then I suspect that there are no numbers in the n^{th} row that are divisible by 3. Surely there are consecutive triangular numbers divisible by 3.

An accountancy of the natural numbers

I guess this formula is known since I believe it's true $$\sum_{k=2}^\infty\frac{(-1)^{1+\Omega(k)}}{k}=1$$ where $\Omega(k)$ is the number of prime factors of k (not necessary different primes). I can't find it and want a formal proof or a reference. My intuition about this sum is something like this: The probability of a number to have the prime factor p is $\frac{1}{p}$ and to have the prime factors p or q is $\frac{1}{p}+\frac{1}{q}-\frac{1}{pq}$ etc. The probability of a number >1 to have a prime factor is 1. Is this sum really not known? Haven't anything been published about it before? I finally realize that the series $$\sum_{k=1}^\infty\frac{(-1)^{\Omega(k)}}{k}=0$$ has been known for a long time, and that solves my confusion.

Who is credited with the conjecture that all odd squares are solitary?

Let $\sigma(x)$ be the sum of the divisors of the positive integer x. For example, $\sigma(6)=1+2+3+6=12$ and $\sigma(28)=1+2+4+7+14+28=56$. Denote the abundancy index I of x by $$I(x)=\frac{\sigma(x)}{x}.$$ If a positive integer y is one of at least two solutions of $$I(y)=\frac{a}{b}$$ for a given rational number a/b, then y is called a friendly number. Here is a formal definition: DEFINITION. Let x and y be distinct positive integers. If x and y satisfy the equation $I(x)=I(y)$ then (x,y) is called a friendly pair. Each member of the pair is called a friendly number. (In other words, x is a friend of y, and y is also a friend of x.) A number which is not friendly is called a solitary number. Checking the first few odd squares N gives us $\gcd(N,\sigma(N))=1$, which by Greening's Theorem means that such N are solitary. Since Greening's Theorem that $\gcd(N,\sigma(N))=1$ implies that N is solitary. is sufficient (but not necessary), "it's easy to find odd squares for which $\gcd(n, \sigma(n))$ is not equal to 1; e.g. if $n = {21}^2 = 441$ then $\gcd(n, \sigma(n)) = 3$. But 441 is solitary." (Dean Hickerson, personal communication via e-mail, Mar. 12, 2011) Here is my question: Who is credited with the conjecture that all odd squares are solitary?

If $N = q^k n^2$ is an odd perfect number with Euler prime q, does the following implication hold?

Let $\sigma(x)$ denote the sum of the divisors of x. For example, $\sigma(6)=1+2+3+6=12$. Numbers N satisfying the equation $\sigma(N)=2N$ are called perfect numbers. Euler showed that an odd perfect number must have the form $N = q^k n^2$ where q is prime with $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Here is my question: If $N = q^k n^2$ is an odd perfect number with Euler prime q, does the following implication hold? $$\bigg(q^k < n \iff \sigma(q^k) < \sigma(n) \iff \dfrac{\sigma(q^k)}{n} < \dfrac{\sigma(n)}{q^k}\bigg) \implies \left(q^k < n\right)$$ From an answer to this earlier MSE question, I know that the converse $$\left(q^k < n\right) \implies \bigg(q^k < n \iff \sigma(q^k) < \sigma(n) \iff \dfrac{\sigma(q^k)}{n} < \dfrac{\sigma(n)}{q^k}\bigg)$$ holds.

Irrationality of the Riemann zeta-function on odd arguments

It is proved that infinitly many of the numbers $\zeta(2n+1)$ are linearly independent over $\mathbb{Q}$. Is there a conjecture such as 'the numbers $\zeta(2n+1)$ are linearly independent over $\mathbb{Q}$'? Thank you!

A property of v

Let n be a natural number. Denote by $v(n)$ the sum of the numbers appearing in the canonical factorization of n (like in A curious property of integers). Then I believe that for $n>1$ the sequence $ n, v(n), v(v(n)), v(v(v(n))),\ldots $ is eventually the same prime number. Was this stated anywhere?

A general criterion of convergence of series?

Given a non degenerated function $f:\mathbb N^+\to\mathbb Z_2 $. (It doesn't stabilize and become constant for all n larger than some natural number). Define the function $\sigma(i,n,f)=|f^{-1}(i)\cap\mathbb Z_n|\,$ and $c_n= \left\{ \begin{array}{l} a_{\sigma(o,n,f)}\;\text{ if } f(n)=0\\ b_{\sigma(1,n,f)}\;\text{ if } f(n)=1 \end{array} \right. $ Then $(c_n)_n$ is a shuffle of $(a_n)_n$ and $(b_n)_n$ for each function f as above. All the terms a_i and b_i occur exactly once in the sequence $c_1,c_2,\dots$ in preserved index order. I would like to formulate this conjecture: If $\displaystyle a=\sum^\infty_{i=1} a_i\;$ and $\displaystyle \; b=\sum^\infty_{i=1} b_i\;$ are convergent and c_i arise from a shuffle of a_i and b_i, then $\displaystyle a+b=\sum^\infty_{i=1} c_i$. I'm asking for a proof of the conjecture or a counterexample and will award the three first correct answers with a bounty worth 200.

A conjecture on tensor product vectors

Consider a real vector space $V^{(1)}\otimes V^{(2)}$ where $\otimes$ is the tensor product. Product vectors are of the form $v_1\otimes v_2$ where $v_1\in V^{(1)}$, $v_2\in V^{(2)}$, anything else is a non-product vector. I conjecture the following I have a set of product vectors $a_i\otimes b_i$, $i=1,\dots,n$ that sum to make a product vector $A\otimes B$, $A\otimes B=\sum_i \alpha_i a_i \otimes b_i$ where α_i are real, non-zero constants and there are no repetitions of a_i. All of these product vectors must have $b_i= \lambda \, B$ $\forall$ i, where λ is some non-zero real. I believe this is true, but am not sure how to proceed. For example, if $n=2$, then $A\otimes B=a_1\otimes b_1 + a_2 \otimes b_2$ is not a product vector unless $a_1=a_2$ or $b_1 =b_2$, and then it is clear that either $a_1=a_2=A$ or $b_1=b_2=B$

Is any mathematican more famous for their conjecture(s) than their theorem(s)?

I'm wondering if some mathematicians gained more fame from their (perhaps visionary) conjectures, than from the positive results they proved? I would say this is not true of Fermat, despite his famous eponymous conjecture (now settled), because he established so many results independent of his conjecture. And this seems not true of Poincaré, whose famous conjecture (also now settled) bears his name. But he was incredibly accomplished independent of that conjecture. Atiyah has formulated wonderfully productive conjectures (one leading to a Witten advance), but he has also established major results, e.g., the Atiyah-Singer theorem. I am interested to explore whether some mathematicians have specific conjecture-talent that is not evidently reflected in theorem-proving talent.

Does a basis b exist such that only a finite number of palindromes in base b are primes?

Can we prove that a base b must necessarily exist so that only a finite number of palindromes in base b are primes? My friend came up with this, I hope it isn't one of those ubiquitous "innocent" number theory problems which are years beyond any hope for solution. So far our ideas have not yielded any fruits: The number of palindromes under n is roughly $\sqrt{n}$ The number of primes under n is roughly $\frac{n}{\log n}$ Any such prime must have odd length (work $\bmod b+1$)

Solving a high school conjecture

Right, so this was something I stumbled upon whilst looking at forms of the golden ratio (if you replace x with one in the diagram above then you get phi) and then I wondered about what if you messed with the value of x, did a massive amount of trial and error (lost in a notebook somewhere) then came up with the equation in the right, which worked exactly for every value I tested (about up to 100) Now I have found stack exchange, in wondering if there is a way to prove this, I plugged in some values into wolfram alpha and geogebra, which seems to show it works, but I want a proof, not just trial and error answers.

Complete monotonicity of a sequence related to tetration

Let Δ denote the forward difference operator on a sequence: $$\Delta s_n = s_{n+1} - s_n,$$ and Δ^m denote the forward difference of the order m: $$\Delta^0 s_n = s_n, \quad \Delta^{m+1} s_n = \Delta\left(\Delta^m s_n\right).$$ We say that a sequence s_n is completely monotone iff $$(-1)^m \Delta^{m} s_n > 0,$$ i.e. the sequence s_n itself is positive and decreasing, its first differences Δs_n are negative and increasing (that is, decreasing in absolute values), its second differences $\Delta^2 s_n$ are positive and decreasing (like the sequence s_n itself), and so on. So, the sequence of second differences of a completely monotone sequence is also completely monotone (and so is the sequence of its differences of any even order). Let a be a real number in the interval $1<a<e^{1/e}$. Let ${^n a}$ denote tetration: $${^0 a}=1, \quad {^{(n+1)} a} = a^{\left({^n a}\right)}.$$ The sequence ${^n a}$ is strictly increasing and converges to the limit $${^\infty a} = \lim_{n\to\infty}\left({^n a}\right) = \frac{W(-\ln a)}{-\ln a},$$ where $W(x)$ is the Lambert W-function. Let $s_n = {^\infty a} - {^n a}$. It appears that the sequence s_n is completely monotone. How can we prove it?

High School Calculus: Find cut out length x which gives Maximum volume of can.

This is a pretty long question so I will try to shorten it as much as possible. Part A: Given: a square piece of tin plate with side length l, cut out corners with shape of square of side length x. Fold the resulting shape into an open-ended cuboid. Determine x for maximum volume (deduce conjecture) Next, prove, using the principles of calculus (and the quadratic formula),the conjecture. Pictues of the problem that I drew: https://i.sstatic.net/YvXk5.png What I did: $V(x)=Length×Width×Height$ (Equation for cuboid) $V(x)=x(l-2X)(l-2x)$ (substitute known values) $=x[(l-2X)]^2$ $=x[(l-2X)]^2$ $=x(l^2-4lx+4x^2)$ $=l^2 x-4lx^2+4x^3$ $V'(x)=l^2-8lx+12x^2$ (differentiate) $0=l^2-8lx+12x^2$ ($V'(x)=0$ to find out maximum/minimum) $0=(2x-l)(6x-l)$ (factorise) $2x-l=0$ $2x=l$ $x=l/2$ (first answer is not correct, if $x=1/2$ then cuboid cant even be made) $6x-l=0$ $6x=l$ $x=l/6$ (correct answer) I am unable to do the next part, Im not sure if i am overthinking it or not. But I cant seem to figure out how do i prove this conjecture? Haven't i already proved it? Part B https://i.sstatic.net/jxYWf.png It ask the same thing as above x when volume is at maximum, however, as you can see from this picture. This time it is a rectangular plate with side length r and s. What I did: $V(x)=x(r-2x)(s-2x)$ (substitute values into equation) $=x(rs-2rx-2sx+4x^2)$ $=rsx-2rx^2-2sx^2+4x^3$ $V'(x)=rs-4rx-4sx+12x^2$ (differentiate) $=rs-4x(r+s)+12x^2$ $=12x^2-4x(r+s)+rs$ $0=12x^2-4x(r+s)+rs$ (set $V'(x)$ as 0 to find out maximum/minimum) $x=(--4(r+s)±√([(-4(r+s))]^2-4\times12rs))/(2\times12)$ (use quadratic formula as it is impossible to factorize) $x=(4(r+s)±√([(-4(r+s))]^2-48rs))/24$ $=(4(r+s)±√([16(r+s)]^2-48rs))/24$ $=(4(r+s)±√([16[(r+s)]^2-3rs]))/24$ $=(4(r+s)±4√([(r+s)^2-3rs]))/24$ $=((r+s)±√([(r+s)]^2-3rs))/6$ $=((r+s)±√(r^2+2rs+s^2-3rs))/6$ $=(r+s±√(r^2-rs+s^2))/6$ And from what I think (only when the $+√(r^2-rs+s^2$)gives the maximum volume) But again, I am suppose to prove the conjecture that I just deduced. Just How? Any advice are welcome.

Is there a maximal prime number not being a sum of consecutive primes?

Let $\mathcal S=\{p\in\mathbb P|\exists m,n\in\mathbb Z_+:p=p_n+\cdots+p_{n+m}\}$. For "small" primes, not much greater than one million, it seems that about half of the primes belong to $\mathcal S$. But the greater primes the more combinations of consecutive primes available. There are $\pi(p)$ primes less than or equal to p and the number of available prime sequences is $1\cdot\pi(p)+2\cdot(\pi(p)-1)+3(\pi(p)-2)+\cdots+(\pi(p)-1)\cdot 2=$ $\displaystyle\frac{\pi(p)^3+3\pi(p)^2+4\pi(p)}{6}$ (If I calculated it right). I suppose it's possible to use the Prime Number Theorem to estimate the probability of $p\in\mathcal S$, but I'm pretty sure that I would mess it up. My questions are: Does $P(p\in\mathcal S)\to 1$ as $p\to\infty$? Can it be proved that there is a maximal prime number not being a sum of consecutive primes? See also How often is a sum of k consecutive primes also prime? which is a similar but not an equivalent question. This is what I got so far. It doesn't support my intuition, but I will let it run up to $10,000,000$ or more.

Why does the same convergent (relative to the period) of the continued fraction of $\sqrt{n}$ give solutions to the Pell equation?

Let n be a natural number which isn't a square and $$\sqrt{n}=[a_0;\overline{a_1,a_2\dotsb a_r}]$$ then consider the convergents $$\frac{x_1}{y_1}=[a_0;a_1,a_2\dotsb a_{r-1}]$$ $$\frac{x_2}{y_2}=[a_0;a_1,a_2\dotsb a_{r-1},a_r,a_1\dotsb a_{r-1}]$$ etc I conjecture that $x_k^2-ny_k^2=\pm 1$. And that all solutions of the positive and negative Pell equations have this form. If $p^2-nq^2=1$ then $0<\frac{p}{q}-\sqrt{n}<\frac{1}{2\sqrt{n}q^2}$. And if $p^2-nq^2=-1$ then $0<\sqrt{n}-\frac{p}{q}<\frac{1}{2\sqrt{n}q^2}$. In both cases $q^2\left|\frac{p}{q}-\sqrt{n}\right|<\frac{1}{2\sqrt{n}}$, so $\frac{p}{q}$ is in some sense a very good approximation of $\sqrt{n}$, and the last number in the period, a_r seems to always be $2\lfloor\sqrt{n}\rfloor$ and larger than all of $a_1,a_2\dotsb a_{r-1}$, so the next best rational approximation of $\sqrt{n}$ would have a "much" bigger denominator than q, so it should make sense for the solutions to the Pell equation to appear before a_r. $$\sqrt{397}=[19;\overline{1,12,3,4,9,1,2,1,2,1,1,2,1,2,1,9,4,3,12,1,38}]$$ $$\frac{20478302982}{1027776565}=[19;1,12,3,4,9,1,2,1,2,1,1,2,1,2,1,9,4,3,12,1]$$ This is the fundamental solution of the negative Pell equation $$20478302982^2-397\times 1027776565^2=-1$$ Getting the second convergent of this type $$\frac{838721786045180184649}{42094239791738433660}=[19;1,12,3,4,9,1,2,1,2,1,1,2,1,2,1,9,4,3,12,1,38,1,12,3,4,9,1,2,1,2,1,1,2,1,2,1,9,4,3,12,1]$$ Gives the fundamental solution to the positive Pell equation $$838721786045180184649^2-397\times 42094239791738433660^2=1$$ It is hard not to prove by induction that the convergents of this form alternate between generating solutions to the positive and negative equations, although very laborious. I have also proven this for the first 20 naturals, 61, and 92. So that's a bit of computational evidence. Heuristically it seems far too unlikely that the conjecture isn't true. If the conjecture is true then the numbers for which the negative Pell equation has a solution are those with an even number of numbers in their period, in particular primes congruent to 1 mod 4.

A nice pattern for the regularized beta function $I(\alpha^2,\frac{1}{4},\frac{1}{2})=\frac{1}{2^n}\ $?

In this post, the problem was given integer/rational N, to solve for algebraic number z in the equation, $$\begin{aligned}\frac{1}{N} &=I\left(z^2;\ a,b\right)\\[1.5mm] &= \frac{B\left(z^2;\ a,b\right)}{B\left(a,b\right)} \end{aligned} $$ using the beta function $B(a,b)$, incomplete beta $B(z;a,b)$ and regularized beta $I(z;a,b)$. It seems for some $a,b,$ there can be a pattern for the solutions. Given the equation for $n>1$, $$I\left(x_1^2;\ \tfrac14,\tfrac12\right)=\frac{1}{2^n}\tag1$$ First define $\color{blue}{\gamma = u+\sqrt{-1+u^2}},$ with fundamental unit $u=1+\sqrt{2}.\ $ Then, For $n=2$: $$x_1=x_2-\sqrt{1+x_2^2},\quad \color{blue}{x_2 =\gamma}$$ For $n=3$: $$x_1=x_2-\sqrt{1+x_2^2},\quad \color{green}{x_2 = x_3+\sqrt{-1+x_3^2},\quad x_3=x_4+\sqrt{1+x_4^2},}\quad \color{blue}{x_4 = \gamma}$$ For $n=4$: $$x_1=x_2-\sqrt{1+x_2^2},\quad x_2 = x_3+\sqrt{-1+x_3^2},\quad x_3=x_4+\sqrt{1+x_4^2},\\ \quad \color{green}{x_4 = x_5+\sqrt{-1+x_5^2},\quad x_5=x_6+\sqrt{1+x_6^2},}\quad \color{blue}{x_6 = \gamma}$$ and so on, where we add the same two nested layers (in green) each time and so end with even index x_m. Questions: Does this pattern really hold for all 2^n and $n>1?$ Why the regularity? What is the integral associated with (1) similar to the ones in the post cited above?

Prove that if $n \mid 1 + \sum_{k=0}^{n-1} k^{n-1}$ then n is prime.

How can I show that if $$n \mid 1 + \sum_{k=0}^{n-1} k^{n-1}$$ then n is prime? I was able to prove that n must be squarefree as follows: since $n \mid 1 + \sum_\limits{k=0}^{n-1} k^{n-1}$ then $\sum_\limits{k=0}^{n-1} k^{n-1} \equiv -1 \pmod n.$ Suppose some prime $p \mid n$, and let $q = n/p$. Now $\sum_\limits{k=0}^{n-1} k^{n-1} \equiv -1 \pmod p$, so $$\sum_{k=0}^{n-1}k^{n-1} = \sum_{m=0}^{q-1}\sum_{k=0}^{p-1}(mp+k)^{n-1} \equiv \sum_{m=0}^{q-1}\sum_{k=0}^{p-1}k^{n-1} = q\sum_{k=0}^{p-1}k^{n-1} \equiv -1 \pmod p.$$ Since -1 is a unit in $\mathbb Z/p\mathbb Z$, then so must be q, so since p is prime we have $p \nmid q$, and thus $p \mid n$ but $p^2 \nmid n$. I have not been able to show that n must be prime. By reducing exponents using Fermat's Little Theorem, I can show that for every prime $p \mid n$ (again $q = n/p$) we have $$q \sum_{k=0}^{p-1} k^{q-1} \equiv -1 \pmod p$$ but I am not sure how to deduce (if it is even possible) that for some $p \mid n$ we must have $q = 1$ (which would immediately imply $n = p$).

How to show an infinite number of algebraic numbers α and β for $_2F_1\left(\frac13,\frac13;\frac56;-\alpha\right)=\beta\,$?

(Note: This is the case $a=\frac13$ of ${_2F_1\left(a ,a ;a +\tfrac12;-u\right)}=2^{a}\frac{\Gamma\big(a+\tfrac12\big)}{\sqrt\pi\,\Gamma(a)}\int_0^\infty\frac{dx}{(1+2u+\cosh x)^a}.\,$ There is also $a=\frac14$ and $a=\frac16$.) In a post, Reshetnikov considered some integrals and the surprising evaluations, $$ \frac{1}{48^{1/4}\,K(k_3)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[3]{x^2+\color{blue}{4}x^3}}=\,_2F_1\big(\tfrac{1}{3},\tfrac{1}{3};\tfrac{5}{6};-\color{blue}{4}\big)= \frac3{5^{5/6}}\tag1$$ $$ \frac{1}{48^{1/4}\,K(k_3)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[3]{x^2+\color{blue}{27}x^3}}=\,_2F_1\big(\tfrac{1}{3},\tfrac{1}{3};\tfrac{5}{6};-\color{blue}{27}\big)=\frac{4}{7}\tag2$$ We postulate these are just the first of an infinite family of algebraic numbers α and β such that, $$_2F_1\left(\frac13,\frac13;\frac56;-\alpha\right)=\beta\tag3$$ $$\begin{array}{|c|c|c|c|c|} \hline p&\tau&\alpha&\beta&\text{Deg}\\ \hline 3&\frac{1+3\sqrt{-3}}2& \large \frac13& \large \frac{2}{3^{2/3}}&1\\ 5&\frac{1+5\sqrt{-3}}2&\color{blue}{4}& \large\frac3{5^{5/6}} &1\\ 7&\frac{1+7\sqrt{-3}}2&\color{blue}{27}&\large\frac47&1\\ 11&\frac{1+11\sqrt{-3}}2& \sqrt{11}\big(2\sqrt3 + \sqrt{11}\big)^3& \large\frac6{11^{11/12}} \frac1{U_{33}^{1/4}} &2 \\ 13&\frac{1+13\sqrt{-3}}2& 4\sqrt{13}\big(4 + \sqrt{13}\big)^3&\large\frac7{13}\frac1{U_{13}}&2\\ 17&\frac{1+17\sqrt{-3}}2& \frac4{729}\left[(1 + \sqrt[3]{17})^2 + 6\right]^6& \large\frac9{17^{5/6}}\left(\frac{18}{17^{1/3}}-7\right)^{1/3}&3\\ 19&\frac{1+19\sqrt{-3}}2& \frac1{27}\left[(1 + \sqrt[3]{19})^2 + 5\right]^6 &\large \frac{10}{19} \Big(1-\frac{(1-19^{1/3})^2}{3}\Big)&3\\ 29&\frac{1+29\sqrt{-3}}2& 4(u_1)^6&\frac{15}{29^{5/6}}(u_2)^{1/3} &5\\ 31&\frac{1+31\sqrt{-3}}2& \frac1{27}(v_1)^6 &\frac{16}{31} (v_2)&5\\ \hline \end{array}$$ and so on, where $U_{13} = \frac{3+\sqrt{13}}2$, $U_{33} = 23+4\sqrt{33}\,$ are fundamental units, while u_i and v_i are roots of quintics, etc. (While the quintics were solvable in radicals, unfortunately they don't have the simple form as the others. The original forms for $p=17,19$ were found by yours truly while alternative ones were suggested by Reshetnikov.) And Deg is degree of $\alpha(\tau)$ and $\beta^6(\tau)$. Conjecture 1: Let $\tau = \frac{1+p\sqrt{-3}}{2}$. Using the Dedekind eta function quotient $\lambda=\frac{\eta\big(\tfrac{\tau+1}{3}\big)}{\eta(\tau)}$, then α is just a quadratic, $$16\cdot27\,\alpha(1+\alpha)=\left(\lambda^6 -27\, \lambda^{-6} \right)^2$$ or more simply, $$\alpha = \frac1{4\sqrt{27}}\big(\lambda^3-\sqrt{27}\,\lambda^{-3}\big)^2\tag4$$ And if $p=6k\pm1$ is a prime, then α and β^6 of (3) are algebraic numbers of degree k. Alternatively, one can use the well-known j-function $j(\tau)$, $$j(\tau) = {1 \over q} + 744 + 196884 q + 21493760 q^2 + 864299970 q^3+\dots$$ which is easily calculated in Mathematica as 12^3KleinInvariantJ[tau]. Conjecture 2: Let $\tau = \frac{1+p\sqrt{-3}}{2}$. Then α is an appropriate root of, $$j(\tau) = \frac{432}{1+f}\left(\frac{5+4f}{1 - f}\right)^3,\quad \text{where}\quad f = \frac{2\alpha+1}{2\sqrt{\alpha(1+\alpha)}}$$ P.S. Conjecture 2 is indebted to the answer by Noam Elkies, though the nature of τ which should provide the correct $\alpha(\tau)$ seems to have been left out.

Are these sequences zero for the greatest of twin, cousin, and prime triples and so on?

Let: $$x=2$$ $$(x=2 \text{ gives greater of twin primes})$$ $$(x=4 \text{ gives greater of cousin primes and so on})$$ $$\text{ If }n=k \text{ then } t(n,k)= 1$$ $$\text{ else if } k=1 \text{ then } t(n,k)= 1-\frac{1}{2} \prod _{i=1}^{n-1} t(n,i+k)-\frac{1}{2} \prod _{i=1}^{n-1-x} t(n-x,i+k)$$ $$\text{ else if } n \bmod k=0 \text{ then } t(n,k) = t\left(\frac{n}{k},1\right) \text{ else } 1 \text{ else } 1$$ This is a table starting: As a Mathematica program this is: (*start*) Clear[t, n, k, i, nn, a]; nn = 1000; x = 2; t[n_, k_] := t[n, k] = If[n == k, 1, If[k == 1, (1 - Product[t[n, k + i], {i, 1, n - 1}]/2 - Product[t[n - x, k + i], {i, 1, n - 1 - x}]/2), If[Mod[n, k] == 0, t[n/k, 1], 1], 1]]; Monitor[a = Table[t[n, 1], {n, 1, nn}];, n] Flatten[Position[a, 0]] (*end*) which gives the first column from the table in the picture above: $$a=1,0,0,\frac{1}{2},0,1,0,1,\frac{1}{2},1,\frac{1}{2},1,0,1,\frac{1}{2},1,\frac{1}{2},1,0,1,...$$ The positions of zeros in that sequence a is: 2, 3, 5, 7, 13, 19, 31, 43, 61, 73, 103, 109, 139, 151, 181, 193, 199, 229, 241, 271, 283, 313, 349, 421, 433, 463, 523, 571, 601, 619, 643, 661, 811, 823, 829, 859, 883 which matches sequence https://oeis.org/A006512 in the oeis starting: 5, 7, 13, 19, 31, 43, 61, 73, 103, 109, 139, 151, 181, 193, 199, 229, 241, 271, 283, 313, 349, 421, 433, 463, 523, 571, 601, 619, 643, 661, 811, 823, 829, 859, 883 and known as the greater of twin primes. Looking up the positions that are fractions (not necessarily 1/2, that breaks down later) I get a match with the sequence https://oeis.org/A093514 starting: 4, 9, 11, 15, 17, 21, 23, 25, 29, 33, 37, 39, 41, 45,... The title says it has something to do with the Sierpinski gasket given by the Rule 90 cellular automaton. Unfortunately I don't understand the Pari GP program given by the author. Question: Is it so that sequence a (the first column in the table from the program) is always 0 for $n>3$ if and only if the position is the greater of the twin primes? An example of a prime triplet: $$\text{ If }n=k \text{ then } t(n,k)= 1$$ $$\text{ else if } k=1 \text{ then } t(n,k)= 1-\frac{1}{3} \prod _{i=1}^{n-1} t(n,i+k)-\frac{1}{3} \prod _{i=1}^{n-1-2} t(n-2,i+k)-\frac{1}{3} \prod _{i=1}^{n-1-6} t(n-6,i+k)$$ $$\text{ else if } n \bmod k=0 \text{ then } t(n,k) = t\left(\frac{n}{k},1\right) \text{ else } 1 \text{ else } 1$$ https://oeis.org/A098413 Greatest members p of prime triples (p-6,p-2,p). {2, 3, 5, 7, 13, 19, 43, 73, 103, 109, 199, 229, 283, 313, 463, 619, \ 829, 859, 883} Compared with: {13, 19, 43, 73, 103, 109, 199, 229, 283, 313, 463, 619, 829, 859, 883,...} (*start*)Clear[t, n, k, i, nn, a]; nn = 1000; t[n_, k_] := t[n, k] = If[n == k, 1, If[k == 1, (1 - Product[t[n, k + i], {i, 1, n - 1}]/3 - Product[t[n - 2, k + i], {i, 1, n - 1 - 2}]/3 - Product[t[n - 6, k + i], {i, 1, n - 1 - 6}]/3), If[Mod[n, k] == 0, t[n/k, 1], 1], 1]]; Monitor[a = Table[t[n, 1], {n, 1, nn}];, n] Flatten[Position[a, 0]] (*end*)

Is it cheating to use the sign function when sieving for twin primes?

Let: $$x=2$$ $$t(1,1)=1$$ $$t(2,1)=0$$ $$t(3,1)=0$$ $$\text{ If }n=k \text{ then } t(n,k)= 1$$ $$\text{ if } n>3 \text{ else if } k=1 \text{ then }$$ $$t(n,k)= \text{sgn}((2- \prod _{i=1}^{n-1} t(n,i+k)- \prod _{i=1}^{n-1-x} t(n-x,i+k)) \cdot (2- \prod _{i=1}^{n-1} t(n,i+k)- \prod _{i=1}^{n-1+x} t(n+x,i+k)))$$ $$\text{ else if } n \bmod k=0 \text{ then } t(n,k) = t\left(\frac{n}{k},1\right) \text{ else } 1 \text{ else } 1$$ where $$\text{sgn}(x)$$ is the sign function. This produces a characteristic sequence of non-twin primes for $n>2$ starting: 1, 0, 0, 1, 0, 1, 0, 1, 1, 1, 0, 1, 0, 1, 1, 1, 0, 1, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 1, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 0, 1, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1

\frac{j(\tau)-1728}{j(\tau)}$. Examples: $$_2F_1\left(\tfrac14,\tfrac14;\tfrac12;\,\tfrac{(3-6\sqrt2)^2}{(1+\sqrt2)^4}\right)=\tfrac{3}{4\sqrt2}(1+\sqrt2)$$ $$_2F_1\left(\tfrac16,\tfrac13;\tfrac12;\,\tfrac{25}{27}\right)=\tfrac{3\sqrt3}{4}$$ $$_2F_1\left(\tfrac18,\tfrac38;\tfrac12;\tfrac{2400}{2401}\right)=\tfrac{2\sqrt7}{3}$$ $$_2F_1\left(\tfrac1{12},\tfrac5{12};\tfrac12;\tfrac{1323}{1331}\right)=\tfrac{3\,\sqrt[4]{11}}{4}$$ using $\tau_1=2\sqrt{-4},\;\tau_2=2\sqrt{-3},\;\tau_3=3\sqrt{-2},\;\tau_4=2\sqrt{-1}$, respectively. And so on for any integer $N>1$. II. Type $a+b=c=\color{blue}{\tfrac23}$. $$\begin{aligned} &\,_2F_1\big(\tfrac14,\tfrac5{12};\tfrac23;(1-2\beta_1)^2\big),\quad \color{red}{\beta_1 =\,?} \\[2mm] &\,_2F_1\big(\tfrac16,\tfrac12;\tfrac23;(1-2\beta_2)^2\big),\quad \frac{1}{\beta_2}-1=\sqrt{\frac{-1}{1728}\big(2k+\sqrt{4k^2-1728^2}\big)}\\[2mm] &\,_2F_1\big(\tfrac18,\tfrac{13}{24};\tfrac23;(1-2\beta_3)^2\big),\quad \color{red}{\beta_3 =\,?} \\[2mm] &\,_2F_1\big(\tfrac1{12},\tfrac7{12};\tfrac23;(1-2\beta_4)^2\big),\quad \frac{1}{\beta_4}-1=\frac{-1}{1728}\big(2k+\sqrt{4k^2-1728^2}\big)\end{aligned}$$ and where $k=j(\tau)-864$. Examples: Use $\tau = \frac{1+N\sqrt{-3}}2$, like $\tau = \frac{1+3\sqrt{-3}}2$, $$_2F_1\big(\tfrac16,\tfrac12;\tfrac23;\tfrac{125}{128}\big) =\tfrac43\,2^{1/6}$$ $$_2F_1\big(\tfrac1{12},\tfrac7{12};\tfrac23;\tfrac{64000}{64009}\big) =\tfrac23\,253^{1/6}$$ III. Type $a+b=c=\color{blue}{\tfrac34}$. $$\begin{aligned} &\,_2F_1\big(\tfrac14,\tfrac12;\tfrac34;(1-2\gamma_1)^2\big), \quad\frac1{\gamma_1}-1=\sqrt{\frac1{64}\Big(\tfrac{\sqrt2\,\eta(2\tau)}{\zeta_{48}\,\eta(\tau)}\Big)^{24}}\\[2mm] &\,_2F_1\big(\tfrac16,\tfrac7{12};\tfrac34;(1-2\gamma_2)^2\big),\quad\color{red}{\gamma_2 =\,?} \\[2mm] &\,_2F_1\big(\tfrac18,\tfrac58;\tfrac34;(1-2\gamma_3)^2\big),\quad\frac1{\gamma_3}-1=\frac1{64}\Big(\tfrac{\sqrt2\,\eta(2\tau)}{\zeta_{48}\,\eta(\tau)}\Big)^{24}\\[2mm] &\,_2F_1\big(\tfrac1{12},\tfrac23;\tfrac34;(1-2\gamma_4)^2\big),\quad\color{red}{\gamma_4 =\,?} \end{aligned}$$ where $\zeta_{48} = e^{2\pi i/48}$. Examples: Use $\tau = \frac{1+N\sqrt{-1}}2$, like $\tau = \frac{1+5\sqrt{-1}}2$, $$_2F_1\big(\tfrac14,\tfrac12;\tfrac34;\tfrac{80}{81}\big)=\tfrac95$$ $$_2F_1\big(\tfrac18,\tfrac58;\tfrac34;\tfrac{25920}{25921}\big)=\tfrac35\,161^{1/4}$$ IV. Type $a+b=c=\color{blue}{\tfrac56}$. $$\begin{aligned} &\,_2F_1\big(\tfrac12,\tfrac13;\tfrac56;(1-2\delta_1)^2\big),\quad\;\delta_1 = \delta_2\\[2mm] &\,_2F_1\big(\tfrac13,\tfrac12;\tfrac56;(1-2\delta_2)^2\big),\quad\;\frac1{\delta_2}-1=\sqrt{\frac1{27}\left(\tfrac{\eta\big(\frac{\tau+1}{3}\big)}{\eta(\tau)}\right)^{12}}\\[2mm] &\,_2F_1\big(\tfrac14,\tfrac7{12};\tfrac56;(1-2\delta_3)^2\big),\quad\color{red}{\delta_3 =\,?} \\[2mm] &\,_2F_1\big(\tfrac16,\tfrac23;\tfrac56;(1-2\delta_4)^2\big),\quad\;\frac1{\delta_4}-1=\frac1{27}\left(\tfrac{\eta\big(\frac{\tau+1}{3}\big)}{\eta(\tau)}\right)^{12} \end{aligned}$$ Note: Of course, $_2F_1\big(\tfrac12,\tfrac13;\tfrac56;z\big) =\,_2F_1\big(\tfrac13,\tfrac12;\tfrac56;z\big)\,$ so the first form is superfluous. Examples: Use $\tau = \frac{1+N\sqrt{-3}}2$, like $\tau = \frac{1+5\sqrt{-3}}2$, $$\begin{aligned} &\,_2F_1\big(\tfrac13,\tfrac12;\tfrac56;\tfrac45\big)=\;\tfrac35\sqrt5 \\[2mm] &\,_2F_1\big(\tfrac16,\tfrac23;\tfrac56;\tfrac{80}{81}\big)=\tfrac35\,(9\sqrt5)^{1/3}\end{aligned}$$ with the last one discussed in this post. Q: How do we find the five missing formulas (?) for the variables in red?

How to show an infinite number of algebraic numbers α and β for $_2F_1\left(\frac14,\frac14;\frac34;-\alpha\right)=\beta\,$?

(Note: This is the case $a=\frac14$ of ${_2F_1\left(a ,a ;a +\tfrac12;-u\right)}=2^{a}\frac{\Gamma\big(a+\tfrac12\big)}{\sqrt\pi\,\Gamma(a)}\int_0^\infty\frac{dx}{(1+2u+\cosh x)^a}.\,$ There is also $a=\frac13$ and $a=\frac16$.) In a post, Reshetnikov considered some integrals and their equivalent forms, $$\frac{1}{2\sqrt2\,K(k_1)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[4]{x^3+\color{blue}{3}x^4}}=\,_2F_1\big(\tfrac{1}{4},\tfrac{1}{4};\tfrac{3}{4};-\color{blue}3\big) = \frac{2}{3^{3/4}}\tag1$$ $$\frac{1}{2\sqrt2\,K(k_1)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[4]{x^3+\color{blue}{80}x^4}}=\,_2F_1\big(\tfrac{1}{4},\tfrac{1}{4};\tfrac{3}{4};-\color{blue}{80}\big) = \frac35\tag2$$ Just like for the case $a=\tfrac13$, we postulate these are just the first of an infinite family of algebraic numbers α and β such that, $$_2F_1\left(\frac14,\frac14;\frac34;-\alpha\right)=\beta\tag3$$ The table below summarizes results and show some quartic trends, $$\begin{array}{|c|c|c|c|c|} \hline p&\tau&\alpha(\tau)&\beta(\tau)&\text{Deg}\\ \hline 3&\frac{1+3\sqrt{-1}}2&4\cdot1^4-1=\color{blue}{3}& \large\frac2{3^{3/4}} &1\\ 5&\frac{1+5\sqrt{-1}}2&3^4-1=\color{blue}{80}& \large\frac35 &1\\ 7&\frac{1+7\sqrt{-1}}2&4(2+\sqrt7)^4-1& \large\frac4{7^{7/8}} \frac1{(8+3\sqrt7)^{1/4}} &2\\ 11&\frac{1+11\sqrt{-1}}2&4u^4 - 1 &\large \frac6{11^{11/12}}\Big(\frac{11^{2/3}-(14-6\sqrt3)^{1/3}-(14+6\sqrt3)^{1/3}}{3}\Big) &3 \\ 13&\frac{1+13\sqrt{-1}}2& v^4-1 &\large \frac7{13^{2/3}}\Big(\frac{13^{-1/3}+(-2+6\sqrt3)^{1/3}-(2+6\sqrt3)^{1/3}}{3}\Big) &3 \\ 17&\frac{1+17\sqrt{-1}}2& x_1^4 - 1 & \large \frac9{17}x_2 &4 \\ 19&\frac{1+19\sqrt{-1}}2& 4y_1^4 - 1 & \large \frac{10}{19}y_2^{1/4} &5 \\ \hline \end{array}$$ and fundamental unit $U_7=8+3\sqrt7$, with u,v as the real root of the cubics, $$u^3 - 23u^2 + 15u - 9=0\\v^3 - 67v^2 - 159v - 99=0$$ and x_i as roots of quartics, and y_i as roots of quintics, and so on. Deg is degree of $\alpha(\tau)$ and $\beta^4(\tau)$. Conjecture: Let $\tau = \frac{1+p\sqrt{-1}}{2}$. To find α, define the eta quotient $\displaystyle\lambda=\frac{\sqrt2\,\eta(2\tau)}{\zeta_{48}\,\eta(\tau)}$ with $\zeta_{48} = e^{2\pi i/48}$. Then, like the case $a=\tfrac13$, α also is a quadratic of similar form, $$16\cdot64\,\alpha(1+\alpha)=\left(\lambda^{12} -64\, \lambda^{-12} \right)^2$$ with analogous root, $$\alpha= \frac1{4\sqrt{64}}\big(\lambda^6-\sqrt{64}\,\lambda^{-6}\big)^2\tag4$$ And if $p=4k\pm1$ is a prime, then α and β^4 of (3) are algebraic numbers of degree k. Questions: How do we prove the conjecture? (And the analogous one in the other post?) Is there a third family of this group with infinitely many algebraic numbers α_3 and β_3? $\color{green}{Update}:$ It seems there is a third family. The obvious choices are $a=\frac12$ and $a=\frac16$. For the latter, and using a better search method, I found, $$_2F_1\Big(\frac{1}{6},\frac{1}{6};\frac{2}{3};-\frac{125}3\Big) = \frac{2}{3^{5/6}}$$ See case $a=\frac16$ here.

How to prove $_2F_1\big(\tfrac16,\tfrac16;\tfrac23;-2^7\phi^9\big)=\large \frac{3}{5^{5/6}}\,\phi^{-1}\,$ with golden ratio ϕ?

(Note: This is the case $a=\frac16$ of ${_2F_1\left(a ,a ;a +\tfrac12;-u\right)}=2^{a}\frac{\Gamma\big(a+\tfrac12\big)}{\sqrt\pi,\Gamma(a)}\int_0^\infty\frac{dx}{(1+2u+\cosh x)^a}.\,$ There is also $a=\frac13$ and $a=\frac14$.) After investigating $a=\frac13$ and $a=\frac14$, I wondered if there was for $a=\frac16$. And happily there was, $$\frac{1}{\color{red}{432}^{1/4}\,K(k_3)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[6]{x^5+\color{blue}{\tfrac{125}3}x^6}}=\,_2F_1\big(\tfrac16,\tfrac16;\tfrac23;-\color{blue}{\tfrac{125}{3}}\big)=\frac{2}{3^{5/6}}$$ $$\frac{1}{\color{red}{432}^{1/4}\,K(k_3)}\,\int_0^1 \frac{dx}{\sqrt{1-x}\,\sqrt[6]{x^5+\color{blue}{2^7\phi^9}\, x^6}}=\,_2F_1\big(\tfrac16,\tfrac16;\tfrac23;-\color{blue}{2^7\phi^9}\big)=\frac{3}{5^{5/6}}\phi^{-1}$$ The first was found by computer search and, from previous posts, the denominator with $K(k_3)$ was enough to give me a clue that $\tau=\frac{1+3\sqrt{-3}}2$ was involved. After fiddling around with some equations, a third conjecture can be made, that there is an infinite family of algebraic numbers α and β such that, $$_2F_1\left(\frac16,\frac16;\frac23;-\alpha\right)=\beta$$ Conjecture: "Let $\tau = \frac{1+p\sqrt{-3}}{2}$ with integer $p>1$. Then α is the root of an analogous quadratic, $$16\cdot\color{red}{432}\,\alpha(1+\alpha)=-j(\tau)$$ with j-function $j(\tau)$. And if odd $p=3k\pm1$ is a prime, then α and β^6 are algebraic numbers of degree k." $$\begin{array}{|c|c|c|c|c|} \hline p&\tau&\alpha(\tau)&\beta(\tau)&\text{Deg}\\ \hline 3&\frac{1+3\sqrt{-3}}2&\frac{125}3& \large\frac2{3^{5/6}} &1\\ 5&\frac{1+5\sqrt{-3}}2&2^7\phi^9& \large\frac3{5^{5/6}}\phi^{-1} &2\\ 7&\frac{1+7\sqrt{-3}}2&\Big(\frac{129 + 29\sqrt{21}}2\Big)^3& \large\frac47 \frac1{U_{21}^{1/2}} &2\\ 11&\frac{1+11\sqrt{-3}}2& x_1 & \large\frac6{11} x_2 &4 \\ 13&\frac{1+13\sqrt{-3}}2& y_1 & \large\frac7{13} y_2 &4 \\ \hline \end{array}$$ $U_{21}=\frac{5+\sqrt{21}}2$ is a fundamental unit, while x_i,y_i are roots of quartics which are rather tedious to write down. And so on. Q: How do we prove this conjecture? (And the other two?)

On $\int_0^1\arctan\,_6F_5\left(\frac17,\frac27,\frac37,\frac47,\frac57,\frac67;\,\frac26,\frac36,\frac46,\frac56,\frac76;\frac{n}{6^6}\,x\right)\,dx$

Reshetnikov gave the remarkable evaluation, \begin{align} I&= \int_0^1\arctan{_4F_3}\left(\frac15,\frac25,\frac35,\frac45;\frac24,\frac34,\frac54;\frac{1}{64}\,x\right)\,dx \\ &=\frac{3125}{48}\left(5+3\pi+6\ln2-3\alpha^4+4\alpha^3+6\alpha^2-12\alpha\\-12\left(\alpha^5-\alpha^4+1\right)\arctan\frac1\alpha-6\ln\left(1+\alpha^2\right)\right)\\ &=0.7857194\dots \end{align} where α is a quartic root. However, it seems this can be simplified a bit and generalized. I. $p=5$: Given, $$I(n)=\int_0^1\arctan\,_4F_3\left(\frac15,\frac25,\frac35,\frac45;\,\frac24,\frac34,\frac54;\,\frac{n}{4^4}\,x\right)\,\mathrm dx$$ Is it true that, in general, $$\frac{12n}{5^5}\, I(n) = -12\Big(1\color{blue}-\frac{n}{5^5}\Big)\arctan\frac1\alpha+6\ln\Big(\frac{2}{1+\alpha^2}\Big)+3\pi+P(\alpha)$$ where $P(\alpha)=(1-\alpha)^3(5+3\alpha)$ and α is the largest positive root of the quintic, $$\alpha^5-\alpha^4+\frac{n}{5^5}=0$$ provided real number $n<4^4\,$? (Note: By sheer coincidence, the choice of $n=4$ in the other post caused the quintic to factor.) II. $p=7$: Given, $$J(n)=\int_0^1\arctan\,_6F_5\left(\frac17,\frac27,\frac37,\frac47,\frac57,\frac67;\,\frac26,\frac36,\frac46,\frac56,\frac76;\,\frac{n}{6^6}\,x\right)\,\mathrm dx$$ is it true that, $$\frac{60n}{7^7}\, J(n) = 60\Big(1\color{blue}+\frac{n}{7^7}\Big)\arctan\frac1\alpha-30\ln\Big(\frac{2}{1+\alpha^2}\Big)-15\pi-P(\beta)$$ where $P(\beta) = (1-\beta)^2(27-6\beta-9\beta^2+8\beta^3+10\beta^4)$ and β is the largest positive root of, $$\beta^7-\beta^6+\frac{n}{7^7}=0$$ provided real $n<6^6\,$? Questions: How do we prove the two conjectured equalities? What's the formula for $p=3$? (Mathematica takes too long to evaluate the integral that I couldn't use an integer relations subroutine on it.)

Connecting $\sum\limits_{n=0}^\infty\frac{n!\,(2n)!}{(3n+2)!}$ and $\sum\limits_{n=1}^\infty\frac{1}{n \binom{3n}{n}}$

Define three generalized hypergeometric functions (which differs in the starting numerator in blue): $$A_k =\,_kF_{k-1}\left(\left.\begin{array}{c} 1,\frac{\color{blue}{k-2}}{k-1},\frac{k-1}{k-1},\dots\\ \frac{k+1}{k}, \frac{k+2}{k},\dots \end{array}\right| \frac{(k-1)^{k-1}}{k^k}\right)$$ $$B_k =\,_kF_{k-1}\left(\left.\begin{array}{c} 1,\frac{\color{blue}{k-1}}{k-1},\frac{k}{k-1},\dots\\ \frac{k+1}{k}, \frac{k+2}{k},\dots \end{array}\right| \frac{(k-1)^{k-1}}{k^k}\right)$$ $$C_k =\,_kF_{k-1}\left(\left.\begin{array}{c} 1,\frac{\color{blue}{k}}{k-1},\frac{k+1}{k-1},\dots\\ \frac{k+1}{k}, \frac{k+2}{k},\dots \end{array}\right| \frac{(k-1)^{k-1}}{k^k}\right)$$ The smallest common non-trivial case would then be $k=3$, $$A_3={_3F_2}\left(1,\tfrac12,\tfrac22;\ \tfrac43,\tfrac53;\ \tfrac4{27}\right)$$ $$B_3={_3F_2}\left(1,\tfrac22,\tfrac32;\ \tfrac43,\tfrac53;\ \tfrac4{27}\right)$$ $$C_3={_3F_2}\left(1,\tfrac32,\tfrac42;\ \tfrac43,\tfrac53;\ \tfrac4{27}\right)$$ The first two were addressed in this and this posts by different OPs from different perspectives, but a common approach may be possible. First, let x_n be the roots of $x^k-x+1=0$. Question 1: Is it true, $$\frac{A_k}{(k-1)(k-2)} = \int_1^\infty \frac{-k+(k-1)x}{x^k-x+1}dx =-\sum_{n=1}^k x_n\ln(1-x_n)\tag1$$ Note: This implies a simple solution to the case $k=3$ discussed in by Reshetnikov in this post as, $$\sum\limits_{n=0}^\infty\frac{n!\,(2n)!}{(3n+2)!}= -x_1\ln(1-x_1)-x_2\ln(1-x_2)-x_3\ln(1-x_3) = 0.5179778\dots$$ where the x_n are the three roots of $x^3-x+1=0\;^\color{red}*$ and which is the minpoly of the negated plastic constant. Question 2: Is it true, $$\frac{B_k}{k} = \int_1^\infty\frac1{x(x^k-x+1)}dx=-\sum_{n=1}^k \frac{\ln(1-x_n)}{-k+(k-1)x_n}\tag2$$ Note: This implies a similarly simple solution to the case $k=3$ in this post, $$\sum_{n=1}^\infty\frac1{n\binom{3n}n} = \frac{\ln(1-x_1)}{3-2x_1}+

\frac{\ln(1-x_2)}{3-2x_2}+ \frac{\ln(1-x_3)}{3-2x_3}=0.371216\dots$$ and the x_n again are the three roots of $^\color{red}*$. Question 3: See this post.

When p is an odd prime, is $(p+2)/p$ an outlaw or an index?

Let $\sigma(x)$ denote the sum of the divisors of x, and denote the abundancy index of x as $$I(x) = \dfrac{\sigma(x)}{x},$$ and the deficiency of x as $$D(x) = 2x - \sigma(x).$$ If the equation $I(a)=b/c$ has no solution $a \in \mathbb{N}$, then b/c is said to be an abundancy outlaw. Statement of the Problem When p is an odd prime, is $(p+2)/p$ an outlaw or an index? Preliminary Results The following lemmas are easy to show: Lemma 1. If p is an odd prime, and $(p+2)/p$ is the abundancy index of some integer n, then n is deficient. Lemma 2. If p is odd, then $\gcd(p,p+2)=1$. Lemma 3. If p is an odd prime and $I(n) = (p+2)/p$, then $D(n) = 2n - \sigma(n) \neq 1$. Lemma 4. If p is an odd prime and $I(n) = (p+2)/p$, then $p < n$. Lemma 5. If p is an odd prime and $I(n) = (p+2)/p$, then $\gcd(n,\sigma(n)) \neq 1$. Remarks In fact, one can show that, if p is an odd prime and $I(n) = (p+2)/p$, then $$\sigma(n) = \bigg(\dfrac{n}{p}\bigg)\cdot(p+2)$$ and $$n = \bigg(\dfrac{\sigma(n)}{p+2}\bigg)\cdot(p).$$ (Note that n/p and $\sigma(n)/(p+2)$ are (equal) integers because of Lemma 2.) Consequently, we obtain $$\gcd(n,\sigma(n)) = \dfrac{n}{p} = \dfrac{\sigma(n)}{p+2}.$$ (Note further that both $\gcd(n,\sigma(n)) \leq n/3$ and $\gcd(n,\sigma(n)) \leq \sigma(n)/5$ hold.) Added September 16 2017 Given that $X = A/B = C/D$ ($B \neq 0$, $D \neq 0$, and $B \neq D$), we can make use of the algebraic identity $$\frac{A}{B}=\frac{C}{D}=\frac{C-A}{D-B}$$ to get another expression for $$\gcd(n,\sigma(n)) = \dfrac{n}{p} = \dfrac{\sigma(n)}{p+2}.$$ Indeed, $$\gcd(n,\sigma(n)) = \dfrac{n}{p} = \dfrac{\sigma(n)}{p+2} = \frac{\sigma(n) - n}{2}.$$ This last finding implies that $$\bigg(\frac{\sigma(n) - n}{2}\bigg) \mid n \iff (\sigma(n) - n) \mid (2n) \iff 2n = (\sigma(n) - n){d_1}$$ and $$\bigg(\frac{\sigma(n) - n}{2}\bigg) \mid \sigma(n) \iff (\sigma(n) - n) \mid (2\sigma(n)) \iff 2\sigma(n) = (\sigma(n) - n){d_2}.$$ Note that $2 \mid (\sigma(n) - n)$. Additionally, notice that $$2\gcd\left(n,\sigma(n)\right) = \gcd\left(2n, 2\sigma(n)\right) = \gcd\left((\sigma(n) - n){d_1},(\sigma(n) - n){d_2}\right)$$ $$= \left(\sigma(n) - n\right)\gcd({d_1},{d_2}) \iff \frac{2\gcd\left(n,\sigma(n)\right)}{\left(\sigma(n) - n\right)}=1=\gcd({d_1},{d_2}).$$ In fact, $${d_1} = \frac{2n}{\sigma(n) - n} = p$$ and $${d_2} = \frac{2\sigma(n)}{\sigma(n) - n} = p+2.$$ Double-checking if it is indeed the case that ${d_1}+2={d_2}$: $${d_1} = \frac{2n}{\sigma(n) - n} + 2 = \frac{2n + 2(\sigma(n) - n)}{\sigma(n) - n} = \frac{2\sigma(n)}{\sigma(n) - n} = d_2.$$ So far so good! More is actually true. One can also show that $$p(2n - \sigma(n)) = (p - 2)n$$ so that $$D(n) = (p - 2)\cdot\bigg(\dfrac{n}{p}\bigg) = (p - 2)\cdot\bigg(\dfrac{\sigma(n)}{p + 2}\bigg) = (p - 2)\cdot\gcd(n,\sigma(n)).$$ We therefore conclude that $$\dfrac{D(n)}{n} = \dfrac{p - 2}{p} = \bigg(\dfrac{p - 2}{p + 2}\bigg)\cdot{I(n)}.$$ Added October 8 2017 We deduce that $$\dfrac{p-2}{p}=\dfrac{D(n)}{n}<\dfrac{\phi(n)}{n}<\dfrac{n}{\sigma(n)}=\dfrac{p}{p+2},$$ whence there is still no contradiction. Motivation It is conjectured that $(p+2)/p$ is an outlaw, since if it were an index, then we would be able to produce an odd perfect number for $p=3$. Here is my question: To what extent can the following theorem be improved to hopefully produce some results towards proving the aforementioned conjecture? Theorem If n is a positive integer satisfying $D(n) = 2n - \sigma(n) > 1$, then we have the following bounds for the abundancy of n in terms of the deficiency of n: $$\dfrac{2n}{n + D(n)} < I(n) < \dfrac{2n + D(n)}{n + D(n)}.$$

If $q^k n^2$ is an odd perfect number with Euler prime q, does $I(n^2) \geq 5/3$ imply $k=1$?

Let $\sigma(x)$ denote the sum of the divisors of $x \in \mathbb{N}$. Denote the abundancy index of $y \in \mathbb{N}$ by $I(y)=\sigma(y)/y$. If $\sigma(N)=2N$, then N is said to be perfect. Euler proved that every odd perfect number has the form $q^k n^2$ where q is prime (called the Euler prime) with $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. If $k=1$, then since $q \geq 5$, then we have $$I(q)I(n^2)=2 \Longleftrightarrow I(n^2)=\dfrac{2q}{q+1} \geq \dfrac{5}{3}.$$ If $k>1$, then we can use the bound $$I(q^k) < \dfrac{q}{q-1} \leq \dfrac{5}{4}$$ so that $$I(n^2)=\dfrac{2}{I(q^k)} > \dfrac{2(q-1)}{q} \geq \dfrac{8}{5}.$$ Here is my question: If $q^k n^2$ is an odd perfect number with Euler prime q, does $I(n^2) \geq 5/3$ imply $k=1$?

Modular relationship between a number and a copy with removed figures

I want a proof of this conjecture: Given a number n with more than two figures written in a positional base-b numeral system and let n' be a base-b number obtained by removing a consecutive pair of equal b-figures in n. Then $$\,n\!\!\mod (b+1)=\,n'\!\!\mod (b+1)$$ Example: $123345667 \mod 11 = 1245667 \mod 11$ for $b\ge 8$.

A limit related to asymptotic growth of tetration

The tetration is denoted $^n a$, where a is called the base and n is called the height, and is defined for $n\in\mathbb N\cup\{-1,\,0\}$ by the recurrence $$ {^{-1} a} = 0, \quad {^{n+1} a} = a^{\left({^n a}\right)},\tag1$$ so that $${^0 a}=1, \quad {^1 a} = a, \quad {^2 a} = a^a, \quad {^3 a} = a^{a^a}, \, \dots \quad {^n a} = \underbrace{a^{a^{{.^{.^{.^a}}}}}}_{n\,\text{levels}}.\tag2$$ Let a be a real number in the interval $e^{-e} < a < e^{1/e}$. It is known that the following limit exists $$L(a) = \lim_{n\to\infty} {^n a},\tag3$$ where $L(a)$ satisfies $a^{L(a)}=L(a)$. For example, $L\left(\!\sqrt2\right)=2$. It is also known that $$\lim_{n\to\infty} \, \frac{L(a) -

{^{n+1} a}}{L(a) - {^n a}} = \ln L(a).\tag4$$ Finally, it is known that the following limit exists $$C(a) = \lim_{n\to\infty} \, \frac{L(a) - {^n a}}{\left(\ln L(a)\right)^n}.\tag5$$ Apparently, no closed form for the function $C(a)$ is known. But the numerical evidence suggests the following conjecture (basically, this is the coefficient of the linear term in the Taylor series expansion of $C(a)$ near $a=1$): $$C'(1) = \lim_{a\to1} \, \frac{C(a)}{a-1} \stackrel?= 1.\tag{$\diamond$}$$ How can we prove it? Can we find values of some higher-order derivatives? Are they all integers? Is there a general formula, recurrence or an efficient algorithm to compute them? Related questions: [1][2][3].

Prime gap around p_n

As ${\rm li}(x)\sim \pi(x) $ and Cramer's conjecture predicts that the maximal prime gap around $ p_n $ is $ O(\log^{2}p_n) $, does a strong heuristics suggest that this prime gap is approximately $ \int_{1}^{p_n}\left(\frac{dx}{dy}\right)\frac{dy}{y} $ where $ y=\pi(x) $? Indeed the derivative of $ \log^{2}x $ is $ 2\frac{\log x}{x} $ which is approximately $ \frac{2}{\pi(x)} $.

Two times the sum of two squares is a sum of two squares

For all $a,b\in\mathbb Z$ there are $c,d\in\mathbb Z$ such that $2(a^2+b^2)=c^2+d^2$. The conjecture is tested for $a^2+b^2<1,000,000$ but I have problems with proving it.

Can this heuristic on odd perfect numbers be made rigorous?

Can this heuristic on odd perfect numbers be made rigorous using the "Axiom of Choice"? Preliminaries Euler showed that an odd perfect number, if one exists, must take the form $N=q^k n^2$ where q is prime with $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. (It follows that $q \geq 5$.) Let $\sigma(x)$ be the sum of the divisors of $x \in \mathbb{N}$. Then by definition, $$\sigma(q^k)\sigma(n^2) = \sigma(q^k n^2) = \sigma(N) = 2N = 2 q^k n^2$$ from which it follows that $$I(q^k)I(n^2) = \dfrac{\sigma(q^k)}{q^k}\cdot\dfrac{\sigma(n^2)}{n^2} = 2$$ where $I(x)=\sigma(x)/x$ is the abundancy index of x. Numerics By a well-known formula for the sum of divisors of a prime power, we have $$I(q^k) = \dfrac{\sigma(q^k)}{q^k} = \dfrac{q^{k+1} - 1}{q^k(q - 1)}.$$ This is bounded by $$\dfrac{q+1}{q} = I(q) \leq I(q^k) < \dfrac{q^{k+1}}{q^k(q - 1)} = \dfrac{q}{q - 1}.$$ Now, note that, when $k=1$, we have the bounds $$1 < I(q^k) = \dfrac{q+1}{q} = 1 + \dfrac{1}{q} \leq 1 + \dfrac{1}{5} = \dfrac{6}{5},$$ from which it follows that $$\dfrac{5}{3} \leq I(n^2) = \dfrac{2}{I(q^k)} = \dfrac{2}{I(q)} < 2.$$ Additionally, when $k>1$, we have the bounds $$1 < I(q^k) < \dfrac{q}{q - 1}.$$ Since $$\dfrac{q}{q - 1} = \dfrac{1}{1 - (1/q)}$$ we obtain $$q \geq 5 \iff 1/q \leq 1/5 \iff 1 - (1/q) \geq 4/5 \iff \dfrac{1}{1 - (1/q)} \leq 5/4$$ so that $$1 < I(q^k) < \dfrac{q}{q - 1} \leq \dfrac{5}{4}.$$ This then implies that $$\dfrac{8}{5} < I(n^2) = \dfrac{2}{I(q^k)} < 2.$$ Implications Note that we have proved the following implications: (1) If $N=q^k n^2$ is an odd perfect number with $k=1$, then $I(n^2) \geq 5/3$. (2) If $N=q^k n^2$ is an odd perfect number with $k>1$, then $I(n^2) > 8/5$. Contrapositives (3) Contrapositive of (1) If $N=q^k n^2$ is an odd perfect number with $I(n^2) < 5/3$, then $k>1$. (4) Contrapositive of (2) If $N=q^k n^2$ is an odd perfect number with $I(n^2) \leq 8/5$, then $k=1$. Analysis By (3) and (2), we have $$I(n^2) < 5/3 \implies k>1 \implies I(n^2) > 8/5 \implies 8/5 < I(n^2) < 5/3$$ resulting in no contradiction, since ${8}\cdot{3} = 24 < 25 = {5}\cdot{5}$. By (4) and (1), we get $$I(n^2) \leq 8/5 \implies k=1 \implies I(n^2) \geq 5/3 \implies 5/3 \leq I(n^2) \leq 8/5$$ resulting in a contradiction, since ${5}\cdot{5}= 25 \nleq 24 = {8}\cdot{3}$. This implies that $I(n^2) > 8/5$ is unconditionally true. Now here is the heuristic: Heuristic If we use the "Axiom of Choice" and identify the lower bound $I(n^2) \geq 5/3$ with $k=1$ and similarly identify the lower bound $I(n^2) > 8/5$ with $k>1$, and since assuming the negation of the latter lower bound contradicts (4) and (1) above, does this mean that we can predict $k>1$ to be true? That is, can we "assume" or prove that the following biconditionals hold? $$k=1 \iff I(n^2) \geq 5/3$$ $$k>1 \iff I(n^2) > 8/5$$

Help finding the flaw in this proof

Today I spent my afternoon trying to understand why the Hardy-Littlewood's Second Conjecture is considered as a problem of such a great difficulty. I got a fairly strange result, so I decided to post it here and wait for opinion. So sorry if I made any kind of terrible mistake or so. The conjecture itself states that: $$\pi(x+y) - \pi(x) \le \pi(y).$$ Or, in the same way, $$\frac{\pi(x+y)}{y(y^2-1)} - \frac{\pi(x)}{y(y^2-1)} \le \frac{\pi(y)}{y(y^2-1)}.$$ Then, integrating both parts from 2 to ∞ over the variable y, $$\int_2^\infty \frac{\pi(x+y)}{y(y^2-1)}dy - \pi(x) \frac{\log\big(\frac{4}{3}\big)}{2} < \frac{\log(\zeta(2))}{2}.$$ Integrating by parts in the first integral, $$\pi(x+2)\frac{\log\big(\frac{4}{3}\big)}{2} - \int_2^\infty \frac{\log\big(1-\frac{1}{y^2}\big)}{2}\pi '(x+y) dy - \pi(x) \frac{\log\big(\frac{4}{3}\big)}{2} < \frac{\log(\zeta(2))}{2}.$$ Then $$\log\bigg(\frac{4}{3}\bigg) \left(\pi(x+2) - \pi(x) \right) - \int_2^\infty \log\bigg(1-\frac{1}{y^2}\bigg)\pi '(x+y) dy < \log(\zeta(2)).$$ And, as the difference between both Prime Counting Functions will be at most 1, $$-\int_2^\infty \log\bigg(1-\frac{1}{y^2}\bigg)\pi '(x+y) dy < \log(\zeta(2))-\log\bigg(\frac{4}{3}\bigg) $$ $$-\int_2^\infty \log\bigg(1-\frac{1}{y^2}\bigg)\pi '(x+y) dy < \log\bigg(\frac{\pi^2}{8}\bigg) $$ Which seems to hold true, since the integral seems to monotonically decrease for large x. Where is the flaw? Thank you!

The $\gcd$ operator commutes with functions defined by linear recurrence relations

Given $a,b\in\mathbb Z^+$, and let $F_{a,b}:\mathbb N\to\mathbb N$ be a function such that $F_{a,b}(0)=0$ and $F_{a,b}(n+1)=a\cdot F_{a,b}(n)+b\cdot F_{a,b}(n-1)$. $F_{1,1}$ correspond to the Fibonacci function if $F_{1,1}(1)=1$. Conjecture which I would like to see proved: If a,b are co-prime and $F_{a,b}(1)\in \mathbb Z^+$, then $F_{a,b}(\gcd(m,n))=\gcd(F_{a,b}(n),F_{a,b}(m))$ I guess that some formulation of the conjecture is true for all homogeneous linear recurrence relations with constant coefficients of degree > 1, but I have only (randomly) tested it for degree 2. See also A generalization of a divisibility relation for Fibonacci numbers

A generalization of a divisibility relation for Fibonacci numbers

Given $a,b\in\mathbb Z^+$, and let $F_{a,b}:\mathbb N\to\mathbb N$ be a function such that $F_{a,b}(0)=0$, $F_{a,b}(1)=1$ and $F_{a,b}(n+1)=a\cdot F_{a,b}(n)+b\cdot F_{a,b}(n-1)$. $F_{1,1}$ correspond to the Fibonacci function. Conjecture for which I would like to see a proof: If a,b are co-prime and $p>2$ is a prime that doesn't divide b, then $F_{a,b}\left(p-\left(\frac{a^2+4b}{p}\right)\right)\equiv 0\pmod p$, where $\left(\frac{a^2+4b}{p}\right)$ is the Legendre symbol. I have tested the conjecture with $10,000$ randomly selected a,b,p. Observation: for Fibonacci numbers $a=b=1$ and $a^2+4b=5$. Wikipedia See also The $\gcd$ operator commutes with functions defined by linear recurrence relations I've never been interested in the Fibonacci numbers and when I recently read about them on Wikipedia I realized that all this interesting theorems for Fibonacci numbers could be generalized to linear recurrence relations with constant coefficients. This funny relation $p|F_{p-(\frac{5}{p})}$ promted for an explanation. I guessed that the '5' came from the solution of the characteristic polynomial of the recurrence relation for the Fibonacci relation with the solutions $\frac{1\pm\sqrt{5}}{2}$. Subtracting the greater root from the smaller and square gives 5 and this seems to be correct. For the general case $x_{n+2}-ax_{n+1}-bx_n=0$ the characteristic polynomial is $t^2-at-b=0$ with the solutions $\frac{a\pm\sqrt{a^2+4b}}{2}$. Since I have an excellent system to check hypotheses (BigZ) the conjecture was easy to test computationally.

Do finitely generated ideals have a "dimension"?

In our algebra class, we recently talked briefly about finitely generated modules, and the instructor referred to how even if a R-module admits a basis, we can easily have that different bases of the module are not in bijection with each other. This brought to mind a different question: For a ring R and a finitely generated ideal I, need all minimal generators of I be in bijection? That is, if $S, T \subseteq I$ are two finite sets such that $I = (S) = (T)$, and moreover such that any proper subset of S or T will not generate I (i.e. if S and T are minimal), then does there exist a bijection between S and T? I raised the question with a friend in my class who's often interested in these kinds of questions, and he brought up that any (left) ideal I would carry a natural structure as a (left) R-module, so if there existed a finite ideal I that would induce a module with non-bijective bases, then the answer would be to the negative, but I have no intuition for whether that would be possible. If the answer is in general to the negative, then is there a natural assumption that could be made about R so that the conjecture does hold?

Given polynomial $P(x)$, find polynomial $Q(x)$ that defines the same field with fixed degree terms

A conjecture about polynomials $P(x)$ and $Q(x)$ defining the same field is believed to be true, but unproven: Let $P(x)$ be an n degree polynomial. There exists a polynomial $Q(x)$ of degree n, with fixed of terms from degrees n to $(n/2)$ if n is even, and $(n+1)/2$ if n is odd, and varied terms degrees from $(n/2)-1$ to 0 if n is even, and degrees from $((n+1)/2)-1$ to 0 if n is odd such that $Q(x)$ defines the same field as $P(x)$ and also infinitely many polynomials of this form, but does not have the same discriminant as $P(x)$. Note that the fixed coefficients in $Q(x)$ do not have to necessarily match those in $P(x)$. Example of conjecture (assuming true): Let $P(x)$ $=$ x^3-16x^2+8x+1, since $P(x)$ is a 3 degree, or cubic polynomial, the first 2 coefficients can be fixed in $Q(x)$, and there exists infinitely solutions (a, b) such that $P(x)$ and $Q(x)$ define the same field where: $P(x)$ $=$ x^3-16x^2+8x+1 $Q(x)$ $=$ $4x^3+7x^2+ax+b$ Note the coefficients in any such $Q(x)$ may be chosen at random, and infinitely many polynomials of this form $Q(x)$ would define the same field $P(x)$. Second, can someone please explain an algorithm for solving the example problem assuming conjecture is true? Thanks for looking into this.

Can we prove this conjecture concerning Pell equations?

For every positive integer n, not being a perfect square, denote the fundamental solution of the Pell equation $$x^2-ny^2=1$$ with (a,b). In other words, b is the smallest positive integer such that nb^2+1 is a perfect square. Define $f(n)=b$. Searching for n with large b , I came to the following conjecture : "If $s>46$ is a composite non-square number, there is a prime $p<s$ with $f(p)>f(s)."$ To formulate it in another way : If we write down every non-square s for which we get a new record for the largest number b (for all smaller numbers, we get a smaller b), the only composite numbers that are written down are 10 and 46. The other numbers written down are prime numbers. The conjecture is true for $s\le 10^6$, but can we prove it for all $s>46$?

Is there a Collatz-like sequence ending with $1,1,1,\ldots$?

I found a conjecture of some mathematics teacher. Is this known or solved problem? Is there a non-constant function f such that for any n, iterating $f(n)$ end to the sequence $1,1,1,1,1,\ldots$. By iteration I mean the similar way as in Collatz problem we end to the sequence $2,1,2,1,\ldots$. For example, does the function $f(n)=\begin{cases}n/3\text{ if }n\equiv 0\pmod 3 \\(4n-1)/3\text{ if }n\equiv 1\pmod 3\\(5n-7)/3\text{ if} n\equiv 2\pmod 3\end{cases}$ end to the sequence $\ldots, 1,1,1,\ldots$ This is from the Finnish mathematical journal from college students called Solmu, http://matematiikkalehtisolmu.fi/2017/1/otaksuma.pdf

Consecutive prime powers $p^m<q^n$ such that $q^n-p^m=11$

Define two prime powers $p^m<q^n$, ($m,n\in\mathbb N$) to be consecutive if it doesn't exist a prime power r^k such that $p^m\!<r^k\!<q^n$. It seems that every even number is the difference between two consecutive prime powers, I haven't ran any large tests yet, but what about the odd numbers? Are there two consecutive prime powers $p^m<q^n$ and $i\in\mathbb N^+$ such that $q^n-p^m=11^i$? I have tested all consecutive prime powers less than $10,000,000$ without finding any solution to $q^n-p^m=11^i$. (A pattern seems to suggest that no odd numbers $N\ge 31$ have a solution to $q^n-p^m=N$, consecutive prime powers. But this must be wrong since prime powers has similar asymptotic distribution as the primes).

There exists infinitely many N such that $\{\sum_{n=2}^N\log(n)\}<\varepsilon$

I am wondering whether or not the following result is true: For all $\varepsilon>0$, there exists infinitely many $N\in \mathbb N$ such that $$S_N:=\left\{\sum_{n=2}^N\log(n)\right\}<\varepsilon$$ where $\{\cdot\}$ denote the fractional part, i.e. $\{x\}=x-[x]$. It seems to be true, looking at these drawing of S_N for N up to 100 and $1\,000$ respectively. But I really don't think $1\,000$ is enough to forge an intuition regarding the veracity of the result. I tried a comparison series-integral, to evaluation $\sum_n \log(n)$: $$I_-=\int_2^{N-1}\log (x)\mathrm d x\leqslant \sum_{N=2}\log (n)\leqslant \int_2^{N} \log(x)\mathrm dx=I_+.$$ And we have: \begin{align*}\int_2^k \log (x) \mathrm d x&=[(-1+\log(x))x]_2^k \\ &=(-1+\log (k))k+(1-\log 2)2,\end{align*} so we can find an equivalent of both I_- and I_+: $$\begin{cases} I_-\underset{N\to\infty}\sim N\log N \\ I_+\underset{N\to\infty}\sim N\log N. \end{cases}$$ I then tried to find if $N\log(N)$ was equidistributed modulo 1, which would prove that there is infinitely many N such that $$N\log N-[N\log N]<\varepsilon.$$ It seems true looking a these images for $N\log N$ modulo 1 up to 520, $5\,000$ and $30\,000$ respectively: But I don't know how to prove it. We win if we show that $$\lim_{N\to\infty}\frac 1N\sum_{n=1}^N e^{2\pi i \ell n\log n}=0$$ for all $\ell\in\mathbb Z\setminus \{0\}$ by Weil's criterion, but I can't prove it. Plus, I don't think the equivalent would actually provide a proof of the result, would it? What other approach could be taken?

What is wrong with this proof that there are no odd perfect numbers?

Main Question What is wrong with this proof that there are no odd perfect numbers? The "Proof" Euler proved that an odd perfect number N, if any exists, must take the form $N = q^k n^2$ where q is the Euler prime satisfying $\gcd(q,n)=1$ and $q \equiv k \equiv 1 \pmod 4$. Denote the sum of divisors of $x \in \mathbb{N}$ by $\sigma(x)$, and the deficiency by $D(x)=2x-\sigma(x)$. Finally, denote the abundancy index by $I(x)=\sigma(x)/x$. Consider the quantity $D(q^k)/\sigma(q^k)$: $$\dfrac{D(q^k)}{\sigma(q^k)}=\dfrac{D(q^k)}{q^k}\cdot\dfrac{1}{I(q^k)}=\dfrac{1}{I(q^k)}\cdot\bigg(2-I(q^k)\bigg)=I(n^2)-1.$$ Multiplying both sides by n^2, we get $$\dfrac{D(q^k)\cdot{n^2}}{\sigma(q^k)}=\sigma(n^2)-n^2 \in \mathbb{N}.$$ It is easy to show the following claims: Claim 1 $\sigma(q^k) \nmid D(q^k)$ Proof Suppose to the contrary that $\sigma(q^k) \mid D(q^k)=2q^k - \sigma(q^k)$. This implies that $\sigma(q^k) \leq 2q^k - \sigma(q^k)$, which contradicts $q^k + 1 \leq \sigma(q^k)$. QED Claim 2 $\sigma(q^k) \nmid n^2$ Proof Suppose to the contrary that $\sigma(q^k) \mid n^2$. Then $$\dfrac{n^2}{\sigma(q^k)}=\dfrac{\sigma(n^2)}{2q^k}$$ is an integer, contradicting the fact that $\sigma(n^2)$ is odd. QED Hence, $\sigma(q^k) \nmid \bigg(D(q^k)\cdot{n^2}\bigg)$, contradicting $$\dfrac{D(q^k)\cdot{n^2}}{\sigma(q^k)}=\sigma(n^2)-n^2 \in \mathbb{N}.$$

Has every finite group a minimal presentation?

For a finite group G let $d(G)$ be the minimal number of generators of G and let $r(G)$ be the minimal number such that G has a finite presentation with $r(G)$ relators. Call a presentation with $d(G)$ generators and $r(G)$ relators a minimal presentation. Question: Has every finite group a minimal presentation?

Peculiar pattern concerning primes and semi-primes?

Define the function $f:\mathbb N^+\to\mathbb N^+$ as: $f(n)$ is the least semi-prime pq such that $n+p+q$ is a prime. (One must prove that this really is a function, but it should be and my tests doesn't contradicts that). There is a sequence of numbers $$21\to 14\to 15\to 10\to 9\to 6\to 4$$ such that if $f(n)\neq 4$ is a number in this sequence, then $f(n+1)$ equals to the successor of $f(n)$ in the sequence. This is tested for all values of $n<100,000$. I would like a proof of that f really is a function, that is, for all $n\in\mathbb N^+$ it exists a semi-prime pq with the property that $n+p+q\in\mathbb P$. Also, if anyone can find a counter-example from the peculiar pattern, I would like to see that. And off course, if anyone can explain the pattern I would be very glad.

Is $\frac{b^2 - 1}{\sigma(b^2) - b^2} + 1$ always an odd prime for odd composite b?

Let $\sigma(x)$ be the sum of the divisors of x. Here is my original question: If $\bigg(\sigma(b^2) - b^2\bigg) \mid \bigg(b^2 - 1\bigg)$, is $$\frac{b^2 - 1}{\sigma(b^2) - b^2} + 1$$ always an odd prime for b odd? Preliminary computations using Mathematica show that this must be true. Is it? Added March 18 2017 When $b = p^k$ where p is an odd prime and $k \geq 1$, we have $$\frac{b^2 - 1}{\sigma(b^2) - b^2} + 1 = \frac{\sigma(b^2) - 1}{\sigma(b^2) - b^2} = \frac{\sigma(p^{2k}) - 1}{\sigma(p^{2k}) - p^{2k}} = \frac{p\sigma(p^{2k-1})}{\sigma(p^{2k-1})} = p,$$ validating didgogns's claim in the comments. Hence, I modify my original question slightly as follows: MODIFIED QUESTION If $\bigg(\sigma(b^2) - b^2\bigg) \mid \bigg(b^2 - 1\bigg)$, is $$\frac{b^2 - 1}{\sigma(b^2) - b^2} + 1$$ always an odd prime for b an odd composite?

Does giving a counterexample to a conjecture prove it to be true or false?

If a problem asks me to give a counterexample to a conjecture, am I proving the conjecture true or false by giving a counterexample? I am leening towards proving it false, because if I were to prove it true, it would involve another technique (contradiction, direct, ...)

A new property of Rowland's sequence or there is a counterexample? Each element a_i is a witness of a greater a_j whose index j is always prime

Rowland's sequence, named after Professor Eric Rowland, is defined as: $$a_1=7$$ $$a_n=a_{n-1}+gcd(n,a_{n-1}), n \gt 1$$ Rowland already proved ("A Natural Prime-Generatin Recurrence", Journal of Integer Sequences, Vol.11, 2008, Article 08.2.8) that for any index n of the sequence, the difference $a_{n}-a_{n-1}$ is a prime number or 1. I would like to ask about an observation regarding Rowland's sequence, that might be a new property of the sequence. I found it just by trial and error, but as far I have tested it, it seems to be true up to index $i=498270791$ (after that point the computer calculations are very slow). The questions are at the end of the explanation. Basically the observation is (Expression 1): $$\forall i \ge 2, \ \exists j \gt i \ :\ \lfloor \frac{lcm(1..i)}{a_i} \rfloor \lt a_j \ \ ,\ \ j \in \Bbb P$$ $$ \land \not \exists k \lt j \ :\ \lfloor \frac{lcm(1..i)}{a_i} \rfloor \lt a_k$$ In other words, any a_i ($i \ge 2$) of the sequence seems to be a kind of "witness" or "marker" of a greater element of the sequence, a_j, whose index j is always a prime number. Here is the method of calculation: We take any index $i \ge 2$, and calculate the least common multiple of all the natural numbers up to the index: $lcm(i)$. Then we divide $lcm(i)$ by the current element of the sequence ${a_i}$. Our witness will be the floor of the number resulting of the division at step 2. Now we look for the first element a_j of Rowland's sequence greater than the witness of step 3 (the index j is also greater than i). The index of that number, j, seems to be always a prime number. For instance here is the list of the first 27 primes confirmed by this method (in other words, the index j that is found and is always prime). Some of them are repeated, for instance 2 and 47, because for those cases lcm([1..i])=lcm([1..i+1]) and the floor of the division in those cases is always smaller than the same a_j, and thus the index j is the same prime number: Another way to write the (Expression 1) is using the second Chebyshev function, which is exactly the natural logarithm of the least common multiple of the integers from 1 to n, so for that reason we can write as follows (Expression 2): $$lcm(1..n)=e^{\psi(n)}$$ $$\forall i \ge 2, \ \exists j \gt i \ :\ \psi(i)-log(a_i) \lt log(a_j)\ ,\ \ j \in \Bbb P$$ $$ \land \not \exists k \lt j \ :\ \psi(i)-log(a_i) \lt log(a_k)$$ or $$\forall i \ge 2, \ \exists j \gt i \ :\ \sum_{p^t \le i} p-log(a_i) \lt log(a_j)\ ,\ \ j \in \Bbb P$$ $$ \land \not \exists k \lt j \ :\ \sum_{p^t \le i} p-log(a_i) \lt log(a_k)$$ This is the PARI\GP code, please feel free to use it and modify it: \p200000; print();print("Calculating first 30 Rowland's witnesses:");print();testlimit = 30;current_rowland_seq_element=7;lcm_list=listcreate();listput(lcm_list,1);witnesses_list=listcreate();for(sequence_index=2,testlimit,current_rowland_seq_element=current_rowland_seq_element+gcd(sequence_index,current_rowland_seq_element);listput(lcm_list,sequence_index);listput(witnesses_list,truncate(lcm(lcm_list)/current_rowland_seq_element)););print(witnesses_list);print();print("Starting test:");print();sequence_index=2;current_rowland_seq_element=7;testlimit = 31247916400;was_found_prime=0;for(prospect=1,length(witnesses_list),if(witnesses_list[prospect]>testlimit,break);while(1,if(was_found_prime==0,current_rowland_seq_element=current_rowland_seq_element+gcd(sequence_index,current_rowland_seq_element),was_found_prime=0);if(current_rowland_seq_element>witnesses_list[prospect],print("(timer:",getabstime(),")\tThe index of the closest element of Rowland's sequence greater than:\t",witnesses_list[prospect],"\t is:\t",sequence_index,"\t . Primality test of the index (0=False, not prime / 1:True, is prime).

Result:\t",isprime(sequence_index));print();was_found_prime=1;break;);sequence_index=sequence_index+1;);); It seems quite interesting, but still do not know if there is a counterexample or not. My computer is quite slow, and the calculation of the next prime index will take it around 6 hours (probably my computer will run out of memory, but I am trying). I would like to ask the following questions: Is there a counterexample? If somebody reading this wants to use the PARI\GP code or create a quicker version in another language and try to look for a counterexample would be great. Maybe the observation does not hold for the next still not calculated indexes of the sample list of the picture and included in the PARI\GP code as well. If there is not a counterexample, why is a_i able to be the witness of a greater a_j whose index j is prime? It might be related with the relationship between the recurrence relation used by Rowland's sequence, which is based on the manipulation of the greatest common divisor, gcd, versus the value lcm($[1,i]$). The link of the expression with the second Chebyshev function is also interesting because it is very related with the primes in the interval $[1,i]$. Maybe the reason is very straightforward but I cannot see it. Any insights are very appreciated, thank you!

If $q^k n^2$ is an odd perfect number with Euler prime q, is it possible to have $n\sigma(n)=q\sigma(q^k)$?

QUESTION If $q^k n^2$ is an odd perfect number with Euler prime q, is it possible to have $n\sigma(n)=q\sigma(q^k)$? BACKGROUND If $\sigma(N)=2N$ (where $\sigma(N)$ is the sum of the divisors of N), then N is said to be perfect. (Denote the abundancy index of $x \in \mathbb{N}$ by $I(x)=\sigma(x)/x$.) Euler proved that every odd perfect number has the form $N=q^k n^2$, where q is prime (called the Euler prime) satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. MY ATTEMPT TO ANSWER THE QUESTION Let $N=q^k n^2$ be an odd perfect number with Euler prime q, and assume to the contrary that $n\sigma(n)=q\sigma(q^k)$. Since $\gcd(q,n)=1$, this implies that $$\frac{\sigma(n)}{q}=\frac{\sigma(q^k)}{n} \in \mathbb{N}.$$ Since $\sigma(q^k) \equiv k+1 \equiv 2 \pmod 4$ and n is odd, then $\sigma(q^k) \neq n$. This implies that $$2 \leq \frac{\sigma(n)}{q}=\frac{\sigma(q^k)}{n}.$$ But qn and $q^k n$ are both deficient. This means that $$\frac{\sigma(q)}{n}\cdot{2} \leq \frac{\sigma(q)}{n}\cdot\frac{\sigma(n)}{q} = I(qn) < 2 \implies \frac{\sigma(q)}{n} < 1 \implies q < n,$$ and $$\frac{\sigma(n)}{q^k}\cdot{2} \leq \frac{\sigma(n)}{q^k}\cdot\frac{\sigma(q^k)}{n} = I({q^k}n) < 2 \implies \frac{\sigma(n)}{q^k} < 1 \implies n < q^k.$$ Together, $q < n$ and $n < q^k$ imply that $k > 1$. Additionally, the equation $$n\sigma(n) = q\sigma(q^k)$$ is equivalent to $$\frac{\sigma(n)}{\sigma(q^k)}=\frac{q}{n},$$ which together with $q < n$, implies that $$\sigma(n) < \sigma(q^k).$$ Consequently, we have $$q < \sigma(q) < n < \sigma(n) < q^k < \sigma(q^k)$$ so that $$\frac{\sigma(q)}{n} < 1 < \frac{\sigma(n)}{q}$$ and $$\frac{\sigma(n)}{q^k} < 1 < \frac{\sigma(q^k)}{n},$$ whereupon I do not obtain any contradictions.

Can a Graph Edge participate in more than two Faces?

After learning some very useful Graph Theory in this question (What is the correct term for cycles more fundamental than Simple Cycles?), I realized that in my work I have been considering a conjecture, which I would like to know if it is a theorem. Has this been proven? For planar graphs, any edge of an undirected cyclic graph may participate in a maximum of two faces. Can anyone confirm or correct me?

A conjectured continued fraction for ϕ^ϕ

As I previously explained, I am a "hobbyist" mathematician (see here or here); I enjoy discovering continued fractions by using various algorithms I have been creating for several years. This morning, I got some special cases for a rather heavy expression I was working on, finding the beautiful identities: $$ \phi^\phi \;=\; 2 + \displaystyle\frac{2\left(1-1/\phi\right)/\phi} {2\left(2-1/\phi\right) + \displaystyle\frac{3\left(1-2/\phi\right)/\phi} {3\left(2-1/\phi\right) + \displaystyle\frac{4\left(1-3/\phi\right)/\phi} {4\left(2-1/\phi\right) + \displaystyle\frac{5\left(1-4/\phi\right)/\phi} {5\left(2-1/\phi\right) + \;\ddots }}}} $$ Equivalently $$ \phi^\phi \;=\; 2 + \displaystyle\frac{2/\phi\left(\phi-1\right)} {2\sqrt5 + \displaystyle\frac{3\left(\phi-2\right)} {3\sqrt5 + \displaystyle\frac{4\left(\phi-3\right)} {4\sqrt5 + \displaystyle\frac{5\left(\phi-4\right)} {5\sqrt5 + \;\ddots }}}} $$ where ϕ is the golden ratio. I was very excited to have found this ϕ^ϕ formula and my question is about how original it is: did someone already see it or could I be confident in assuming it is new? Similarly $$ \phi^{2/\phi} \;=\; 2 + \displaystyle\frac{2\left(1-2/\phi\right)} {2\phi + \displaystyle\frac{3\left(1-3/\phi\right)} {3\phi + \displaystyle\frac{4\left(1-4/\phi\right)} {4\phi + \displaystyle\frac{5\left(1-5/\phi\right)} {5\phi + \;\ddots }}}} $$ By using a more compact notation (see at the end of this message for an explanation about how to read it), other identities for $\sqrt{3}$, $\sqrt[3]{4}$, $\sqrt[4]{5}$, etc. would be: $$ \sqrt[a]{a+1} \;=\;2+ \displaystyle\operatorname*{K}_{n=1}^{\infty} \frac {\left(n+1\right)\left(1-an\right)/\left(a+1\right)} {\left(n+1\right)\left(1+a/\left(a+1\right)\right)} $$ These identities are special case of the following conjectured identity (of course, when asking whether the previous formulae are known or not, it also means the formula below should be new also): $$ \left(\displaystyle\frac{x}{x-1}\right)^{x-1} \;=\;2+ \displaystyle\operatorname*{K}_{n=1}^{\infty} \frac {\left(n+1\right)\left(x-n-1\right)/x} {\left(n+1\right)\left(x+1\right)/x} \tag{1}\label{1} $$ that I found from a more general conjecture being related to the following continued fraction: $$ g\left(k,x\right) = \displaystyle\operatorname*{K}_{n=1}^{\infty} \frac {\left(n+1\right)\left(k-n-k/x\right)/x} {\left(n+1\right)\left(1+1/x\right)} $$ for which I empirically noticed the relation (with $\textrm{B}$ the beta function): $$ \begin{array}{l} 2\;+\; g\left(\alpha,\xi\right) \;+\;

g\left(\alpha,\displaystyle\frac{\xi}{\xi-1}\right) \\[8pt] \qquad\qquad =\; \alpha\left(\xi-1\right)^{\alpha/\xi-1}\left(\displaystyle\frac{\xi}{\xi-1}\right)^{\alpha-2} \textrm{B}\left(\alpha/\xi, \alpha-\alpha/\xi\right) \end{array} \tag{2}\label{2} $$ where it is easy to notice that the case $\alpha=\xi/\left(\xi-1\right)$ makes $g\left(\alpha,\xi\right)=0$ leading to an identity containing a single continued fraction (which can later be simplified as above). The previous notation is the one I use; I find it convenient and it can be found for instance in Continued Fractions with Applications by Lorentzen & Waadeland, but I know that some people don't like it; it has to be read the following way: $$ a_0 + \operatorname*{K}_{n=1}^{\infty} \frac{b_n}{a_n} = a_0 + \cfrac{b_1}{a_1 + \cfrac{b_2}{a_2 + \cfrac{b_3}{a_3 + \ddots}}} $$

Correlation matrix inequality conjecture

Let A_{ij} be a correlation matrix, in other words it has the properties that $\forall i\, A_{ii}=1$ $|A_{ij}|\leq1$ $A_{ij}=A_{ji}$ A_{ij} is positive semi-definite, ie. $\forall y_i\,\sum_{ij}A_{ij}y_iy_j\geq 0$ I conjecture that if x_i is any vector of positive values, ie. $\forall i\,x_i\geq 0$, then $$ \forall i\quad\sum_jA_{ij}x_j\leq\sqrt{\sum_{jk}A_{jk}x_jx_k} $$ provided that the RHS is greater than 0 (not sure whether this last condition can be relaxed). Can someone please point me to a proof of this conjecture, or provide a counterexample?

Adding digits in this way to primes to obtain another primes

I just created the following "game": Choose some prime number. If it has k digits then add another k digits to the right to obtain another prime number. Now we have a prime number with $2k$ digits. Now add $2k$ digits to the right of the new number to obtain a new prime number. Repeat the procedure until it is no longer possible to produce new primes in this way. To clarify, let us take for example 5. We must add one digit to the right to obtain another prime number, it can be 53. Now we must add two digits to the right of 53 to obtain a new prime. It could be 5323. Now we must add four digits to the right of 5323 to obtain a new prime. It could be 53231117 and so on and so on... Is it true that whatever prime we choose at the beginning that this game never ends? That is, that it is always possible to build larger primes from the smaller ones in this way?

Is this known about π?

Suppose that we travel along the digits of π and when we arrive at 2 or 3 or 4 or 5 or 6 or 7 or 8 or 9 we replace those digits with the number 1 and when we arrive at 1 or 0 we leave them unchanged. When we do this with all the digits will resulting number be irrational? Since this looks quite hard you can, if you want, assume that π is normal in order to prove this. But I do not know is normality enough? (The statement that we can suppose that π is normal was not in the original version of the question.)

Set conjectures concerning the asymptotic behaviour of erratic arithmetic functions, related to the Möbius function and the Liouville function

I get from an artificious way, but simple, two similar statements that I belive that are true (I had that identify some arithmetic functions), that is my Claim below. In next question I am asking about how to create good conjectures concerning two erratic arithmetic function, that will be introduced in this statement (see my motivation). Motivation. M1) For $n\geq 1$ was defined in the literature the sum of remainders function $$s(n)=\sum_{k=1}^n n\operatorname{mod}k.$$ Professor Spivey did a comparison in [1] between the properties that the sum of divisor function has versus this function. Is known that there are interesting identities with weights involving functions like Pillai function (I try to explore different ways to know more about the sum of remainders function). M2) From simple identities that appears in [2] multiplying by, corresponding the Möbius function $\mu(n)$ or the Liouville function $\lambda(n)$, and taking the sum, I can state the following (notice of the typography $\nmid$ in the first terms of LHS) Claim. A) For each $n\geq 1$ $$\varphi^{-1}(n)+\sum_{\substack{1\leq k\leq n \\ k\nmid n}}\mu(k)(n\operatorname{mod}k)=M(n)+\sum_{1\leq k\leq n}\mu(k)((n-1)\operatorname{mod}k)$$ where $\varphi^{-1}(n)$ is the Dirichlet inverse of Euler's totient function, and $M(n)$ is the Mertens function. B) For each $n\geq 1$ $$f(n)+\sum_{\substack{1\leq k\leq n \\ k\nmid n}}\lambda(k)(n\operatorname{mod}k)=L(n)+\sum_{1\leq k\leq n}\lambda(k)((n-1)\operatorname{mod}k)$$ where $f(n)$ is the Sloane's sequence A061020 (see [3] for the rest of references of our sequences), and $L(n)$ is the summary function $$L(n)=\sum_{k=1}^n\lambda(k).$$ M3) I have curiosity also about how to create good conjectures involving erratic functions. I am asking about how to combine mathematical reasonings, knowledges of the behaviour of the partial sums of Möbius and Liouville functions, and/or experiments with a computer to set conjectures that would be difficult to rule out.$\square$ Question. I was doing experiments and seems that the arithmetic functions defined for integers $n\geq 1$ $$R_1(n):=\sum_{1\leq k\leq n}\mu(k)((n-1)\operatorname{mod}k),$$ and $$R_2(n):=\sum_{1\leq k\leq n}\lambda(k)((n-1)\operatorname{mod}k)$$ are very erratic*. Imagine that I have a friend that ask me about a reasoning/method to get good conjectures about the asymptotic behaviour of these functions as $n\to\infty$. Are possible deductions to set such conjectures using mathematical ideas (reasonings, heuristics, numerical evidence)? What should be such conjectures? Many thanks. *You can see the behaviour of the sequence typying similar codes than these in Wolfram Alpha online calculator: sum mu(k)mod(10000-1,k), from k=1 to 10000 sum LiouvilleLambda(k)mod(50000-1,k), from k=1 to 50000 References: [1] Spivey, The Humble Sum of Remainders Function, Mathematics Magazine Vol. 78, No. 4 (2005). proving of the given conjecture

let us suppose that there is given such kind of conjecture if their division is square of integer then we will have $\frac{a^2+b^2}{ab+1}=k^2$ for some integer k, then we would have $a^2+b^2=k^2*ab+k^2$ or we would have $a^2-k^2*a*b+b^2=k^2$ compare to the equation $a^2-2*a*b+b^2=(a-b)^2$ we would have $k^2=2$ but is that proof ? i could not understand if there is another option or alternative ways

A Conjectured Mathematical Constant For Base-10 Normal Numbers.

Question 1: Let a be a real number with a base-10 decimal representation $a_1a_2\ldots a_n \ldots$ Denote the number of ways to write a_n as the sum of positive integers as $p(a_n)$ - also called the partition of a_n. I write $A(n)=\sum_{k=1}^n p(a_k)$ and $B(n)= \sum_{k=1}^n a_k$ and set $$\beta(a)=\lim_{n\to \infty}{A(n)\above 1.5 pt B(n)}$$ If a is a base-10 simply normal number is it true that $\beta(a)={97 \above 1.5 pt 45}$? Attempted Solution: Let a be a base-10 simply normal number with decimal representation $a_1a_2\ldots a_n \ldots$. Explicitly we can write \begin{equation}\lim_{n\to \infty}{A(n)\above 1.5 pt B(n)} =\lim_{n\to \infty}{p(a_1)+p(a_2)+\ldots +p(a_n)\above 1.5pt a_1+a_2\ldots +a_n }\end{equation} Surely $a_k \in [0,9]$ for every $1\leq k \leq n$. Now let $\nu_n(a_k)$ count occurrences of the digit a_k up to and including the n-th decimal place of a. Observe the following: the numerator in the above equation can be written explicitly as: $$ \underbrace{(p(0)+\ldots +p(0))}_{\nu_n(0)\text{ times}}+\ldots+\underbrace{(p(9)+\ldots + p(9))}_{\nu_n(9)\text{ times}}$$ and similarly the denominator may be written as $$\underbrace{(0+\ldots +0)}_{\nu_n(0)\text{ times}}+\ldots+\underbrace{(9+\ldots + 9)}_{\nu_n(9)\text{ times}}$$ Combining those two observation together we can rewrite the RHS of our first equation as $$ \lim_{n \to \infty}{\nu_n(0)\times p(0)+\nu_n(1)\times p(1)+\ldots + \nu_n(9)\times p(9)\above 1.5pt \nu_n(0)\times 0+ \nu_n(1)\times1+\ldots + \nu_n(9)\times9} $$ Recall that every digit of a occurs with equal frequency. In particular since a is simply normal we have that $\lim_{n \to \infty}\nu_n(a_j)=\lim_{n \to \infty}\nu_n(a_k)$ for every j and k. With out loss to generality we can substitute $\nu_n(j)$ with $\nu_n(1)$ in the numerators and denominators of the equation above and evaluate the limit, $$\lim_{n \to

\infty}{\nu_n(1)\times p(1)+\ldots + \nu_n(1)\times p(9) \above 1.5pt \nu_n(1)\times1+\ldots + \nu_n(1)\times9}$$ We can then pull out the term $ \nu_n(1)$, noticing those terms cancel out in the limit, and make a final simplification to show that $$\lim_{n \to \infty}{\nu_n(1) \above 1.5pt \nu_n(1)}{p(1) +\ldots +p(9)\above 1.5 pt 1+ \ldots +9}={1+1+1+2+3+5+7+11+15+22+30 \above 1.5pt 0+1+2+3+4+5+6+7+8+9}={ 97 \above 1.5pt 45}.$$ I believe the above solution to Question 1 is correct? Now my understanding is that we have the following implication: base-10 normal $\implies$ base-10 simply normal. So the follow up question seems natural. Question 2: If a is a base-10 normal is it true that $\beta(a)={97 \above 1.5 pt 45}$? The answer to Question 2 should be yes by implication alone. Moreover it should be true for both algebraic and transcendental base-10 normal numbers. Since I believe I have shown every base-10 simply normal number converges to ${97 \above 1.5 pt 45}$ under β and every base-10 normal number is simply normal then so to will every base-10 normal number converge to ${97 \above 1.5 pt 45}$ under β. It should be clear that the converse two Question 2 is false ! If we believe Questions 1 and 2 are true then we would expect several well known provably base-10 normal constants to converge to ${97 \above 1.5pt 45}$ under β. So I ran an experiment using data from Sloan's Database on the Erdos-Copeland constants which is proven to be normal in base-10. Using the first $2\text{ }000$ digits I plotted the values of $\beta(\text{Erdos-Copeland})$. The graph below illustrates the convergence. The blue line is the value of ${97 \above 1.5 pt 45}$ and the green graph are the values of the Erdos-Copeland constant under β. Up to the $2\text{ }000$-th digit $\beta(\text{Erdos-Copeland})=2.12999037999\ldots$ I believe given enough terms one can plot a similar graph for the Champernowne constant and one should expect the convergence to be significantly slower. Finally it is not known if π is normal in base-10. Out of curiosity I computed $\beta(\pi)$ up to the first $500\text{ }000$ digits of π. See the graph below. Again the blue line is the value of ${97 \above 1.5 pt 45}$ and the orange graph are the values of the π under β. Up to the $500\text{ }000$-th digit $\beta(\pi)=2.153781\ldots$. π appears to converge faster under β than any other mathematical constant I have looked into. I have numerous plots for zeta values and square roots and they all appear to approach ${97 \above 1.5 pt 45}$ which can be written numerically as $2.15555\ldots$. I have not attempted to plot numbers that are known to be abnormal in base-10.

Squares in $(\operatorname{rad}(1)^2+1)\cdot(\operatorname{rad}(2)^2+1)\ldots(\operatorname{rad}(n)^2+1)$

For integers $n\geq 1$, $\operatorname{rad}(n)$ denotes the radical of an integer, see in Wikipedia this definition $$\operatorname{rad}(n)=\prod_{p\mid n}p,$$ if $n>1$ with factorization $n=\prod_{p\mid n}p^{e_p}$, and defining $\operatorname{rad}(1)=1$. I'm inspired in a similar conjecture due to Amdeberhan, and Medina and Moll. Question. I believe that the following conjecture holds. Can you prove or refute it? There exists an integer N such that $\forall n>N$ $$\prod_{k=1}^n(1+(\operatorname{rad}(k))^2)$$ is not a square. Many thanks. References: Amdeberhan, and Medina and Moll, Arithmetical properties of a sequence arising from an arctangent sum, J. Number Theory (2007).

A Matrix With Eigenvalues Equal to The Golden Ratio and the Golden Conjugate

Question : Let $A(n)$ be a finite square $n \times n$ matrix with entries $a_{i,j}=1$ if $i+j$ is a perfect power; otherwise equals to 0. Can we determine the numbers n such that characteristic polynomial of $A(n)$ has at least two real roots: one equal to the golden ratio and the other equal to the golden conjugate ? For an examlple consider $$A(8)= \text{ }\begin{pmatrix} 0&0&1&0&0&0&1&1\\ 0&1&0&0&0&1&1&0\\ 1&0&0&0&1&1&0&0\\ 0&0&0&1&1&0&0&0\\ 0&0&1&1&0&0&0&0\\ 0&1&1&0&0&0&0&0\\ 1&1&0&0&0&0&0&0\\ 1&0&0&0&0&0&0&1\\ \end{pmatrix}$$ I denote the characteristic polynomial of $A(n)$ by $\chi_{A(n)}(X)$. So for example $$\chi_{A(8)}(X)=X^8-3X^7-5X^6+19X^5+2X^4-31X^3+X^2+10X-3$$ I use the standard notation φ to denote the golden ratio and it is equal to ${1+\sqrt{5}\above 1.5pt 2}$. The "Golden Conjugate" is written as $-{1\above 1.5 pt \varphi}$ and is equal to ${1-\sqrt{5}\above 1.5pt 2}$. I use λ to denote an eigenvalue of $\chi_{A(n)}(X)$. In the example above the characteristic polynomial $\chi_{A(8)}(X)$ has two eigenvalues $\lambda_1=-{1\above 1.5 pt \varphi}$ and $\lambda_2=\varphi$. In particular $\chi_{A(8)}(X)$ has exactly two roots: one equal to the golden ratio and the other equal to the golden conjugate. Below is a tabulation of data for small values of n. Calculations were performed in WOLFRAM ALPHA. The calculations should be correct but errors are inevitable. Only real eigenvalues are listed: \begin{array}{| l | l | l |l|} \hline n & \text{characteristic polynomial} &\text{eigenvalues}\\ \hline 2 & X^2-X & (0,1)\\ 3 & -X^3+X^2+X-1 & (-1,1,1)\\ 4 & X^4-2X^3+2X-1 & (-1,1,1,1)\\ 5 & -X^5+2X^4+2X^3-5X^2+X+1 &(-\lambda_1,\lambda_2,1,1,\lambda_3)\\ \color{blue}{6} & \color{blue}{X^6-2X^5-4X^4+8X^3+2X^2-4X-1} & \color{blue}{(1,-{1\above 1.5 pt \varphi},\varphi,\lambda_1,\lambda_2,\lambda_3)}\\ 7 & -X^7-2X^6+6X^5-11X^4-9X^3+15X^2+2X-4 & (1,\lambda_1,\lambda_2,\lambda_3,\lambda_4,\lambda_5,\lambda_6) \\ \color{blue}{8} & \color{blue}{X^8-3X^7-5X^6+19X^5+2X^4-31X^3+X^2+10X-3} & \color{blue}{(-{1\above 1.5 pt \varphi},\varphi,\lambda_1,\lambda_2,\lambda_3,\lambda_4,\lambda_5,\lambda_6)}\\ \color{blue}{9} & \color{blue}{-X^9+3X^8+6X^7-22X^6-5X^5+45X^4-12X^3-22X^2+5X+3} & \color{blue}{(\lambda_1,\lambda_2,\lambda_3,-\varphi,\varphi,1,-{1\above 1.5 pt \varphi},1-\varphi,\lambda_4)}\\ \hline \end{array} Surely $n=6,8,9$ are shown to answer the question. I am certain that if $A(n)$ has φ as a eigenvalue then it must also have $-{1\above 1.5 pt \varphi}$ as an eigenvalue. The motivation here is an understanding of the matrix $A(n)$. Edit 1: Correction to tabulated eigenvalues when n=6. There are actually 6 real eigenvalues and I listed only 3. Three of the eigenvalues can be written : 1, φ and $1-\varphi$. The other three however have exact forms that can be written with $i=\sqrt{-1}$. $$\lambda_1 = {\sqrt[3]{\frac{1}{2}\bigg(9 + i \sqrt{687}\bigg)}\above 1.5 pt 3^{2/3}} + {4 \above 1.5pt {\sqrt[3]{\frac{3}{2} \bigg (9 + i \sqrt{687}\bigg)}}}$$

$$\lambda_2 = {\bigg(1-i\sqrt{3}\bigg)\sqrt[3]{\frac{1}{2}\bigg(9 + i \sqrt{687}\bigg)}\above 1.5 pt 2\times 3^{2/3}} - {2(1+i\sqrt{3})\above 1.5pt {\sqrt[3]{\frac{3}{2} \bigg (9 + i \sqrt{687}\bigg)}}}$$ $$\lambda_3 = -{\bigg(1+i\sqrt{3}\bigg)\sqrt[3]{\frac{1}{2}\bigg(9 + i \sqrt{687}\bigg)}\above 1.5 pt 2\times 3^{2/3}} - {2(1-i\sqrt{3})\above 1.5pt {\sqrt[3]{\frac{3}{2} \bigg (9 + i \sqrt{687}\bigg)}}}$$ Numerically the eigenvalues λ_1,λ_2 and λ_3 are real - in particular the imaginary terms cancel out. Explicitly $\lambda_1\approx 2.11491\ldots$, $\lambda_2\approx -.618034\ldots$,$\lambda_3\approx -.254102\ldots$ Edit 2: $A(n)$ never has complex eigenvalues for any n. I included the missing eigenvalues in the table. Also I corrected errors in the table for $n=5$. None of the corrections change the result/conjecture of the problem. Namely that $6,8$ and 9 are the only integers such that $A(n)$ has a eigenvalues equal to φ or $-{1\above 1.5 pt \varphi}$. For $n=5$ the corrected values are numerically $\lambda_1 \approx 1.87939\ldots$, $\lambda_2\approx -1.53209\ldots$,$\lambda_3=1$,$\lambda_4=$, $\lambda_5 \approx -0.347296\ldots$ These values have exact forms similar to the radicals shown in Edit 1 above For $n=7$ the 6 missing values are numerically $\lambda_1 \approx 2.38839\ldots$, $\lambda_2\approx -1.9041\ldots$,$\lambda_3\approx 1.77217\ldots$,$\lambda_4\approx -1.33388\ldots$, $\lambda_5 \approx 0.0.64993\ldots$,$\lambda_6 \approx -0.572499 \ldots$. For $n=8$ the 6 missing values are numerically $\lambda_1 \approx 2.48767\ldots$, $\lambda_2\approx -1.98486\ldots$,$\lambda_3\approx 1.77268\ldots$,$\lambda_4\approx -1.39899\ldots$, $\lambda_5 \approx 0.827404\ldots$,$\lambda_6 \approx 0.296099 \ldots$. For $n=9$ the 4 missing values are numerically $\lambda_1 \approx 2.54926\ldots$, $\lambda_2\approx -2.03439\ldots$,$\lambda_3\approx 1.80552\ldots$,$\lambda_4\approx 0.320385\ldots$ These values have exact forms similar to the radicals shown in Edit 1 above. Conjecture: $6,8$ or 9 are the only numbers n such that characteristic polynomial of $A(n)$ has eigenvalues: one equal to the golden ratio and another equal to the golden conjugate.

A conjectured continued fraction related to a 2F1 hypergeometric function (and a formula for π)

In a previous question, some months ago, I described a continued fraction for which I was trying to find an identity. I finally found what I was looking for, and I will publish an answer to this question in the days or weeks to come by focusing to what was asked at that time. But now, I am opening a separate question for a new interest: Could the conjectured statements below be proved? Do these identities sound familiar to anyone? etc. My identity finally is: $$ \begin{array}{lcl} \mathcal{K}\left(a,x\right)&=&\displaystyle\operatorname*{K}_{n=1}^{\infty} \frac{ \left(n+1\right)\left(\left(a-1\right)x-n\right)a}{\left(n+1\right)\left(a+1\right)}\\[12pt] &=& \displaystyle\frac{\left(a-1\right)x-1}{x+1}\; \displaystyle{}_{2}F_{1}\left(1,ax\;; 2+x\;; a^{-1}\right) \end{array} \tag{1} \label{1} $$ Two functional identities I empirically noticed two functional identities, namely: $$ 2+\mathcal{K}\left(a,x\right)+\mathcal{K}\left(1-a,x\right) \;=\; 0 \tag{2} \label{2} $$ and (with $\textrm{B}$ the Beta function): $$ \begin{array}{l} 2+\displaystyle\frac{1}{a}\mathcal{K}\left(a,x\right) +\displaystyle\frac{a-1}{a}\mathcal{K}\left(a/\left(a-1\right), \left(a-1\right)x\right)\\[8pt] \qquad\qquad\;=\; ax\left(a-1\right)^{x-1}\left(\displaystyle\frac{a}{a-1}\right)^{ax-2}\textrm{B}\left(x,\left(a-1\right)x\right) \end{array} \tag{3} \label{3} $$ I already told about the latter in another question. A finite summation While studying the polynomials from the initial question, I finally found the following summation: $$ \mathcal{K}\left(a,x\right)\;=\; \displaystyle\frac{\displaystyle 2\sum_{k=2}^{\left(a-1\right)x-1} \left(k-1\right){{ak/\left(a-1\right)}\choose{k}} {a\left(\left(a-1\right)x-k\right)/\left(a-1\right) \choose{\left(a-1\right)x-k}} } {\displaystyle\left(\left(a-1\right)x-2\right){{ax}\choose{x}}} \tag{4} \label{4} $$ (when $(a-1)x$ is an integer greater than 2). A formula for π I tried several computer algebra systems and found the hyperexpand function in Sympy to be able of simplifying the ${}_2F_1$ hypergeometric function for many rational cases. My favorite case comes from $\mathcal{K}\left(-3, 1/2\right)$, after some cosmetic changes: $$ \pi \;=\; \operatorname*{K}_{n=1}^{\infty} \frac{ 81\left(n+1\right)\left(n+2\right)/16}{3\sqrt{3}\left(n+1\right)/2} \tag{5} \label{5} $$ The formula for ϕ^ϕ in the previous question was also a specific case for the same continued fraction.

If $N=q^k n^2$ is an odd perfect number, which is bigger, $\sigma(n^2)/n^2$ or $\sigma(n)/q^k$?

QUESTION If $N=q^k n^2$ is an odd perfect number, which is bigger, $\sigma(n^2)/n^2$ or $\sigma(n)/q^k$? BACKGROUND If $\sigma(N)=2N$ (where $\sigma(N)$ is the sum of the divisors of N), then N is said to be perfect. (Denote the abundancy index of $x \in \mathbb{N}$ by $I(x)=\sigma(x)/x$.) Euler proved that every odd perfect number has the form $N=q^k n^2$, where q is prime (called the Euler prime) satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. MY ATTEMPT TO ANSWER THE QUESTION Let $N=q^k n^2$ be an odd perfect number with Euler prime q. Suppose that $$\frac{\sigma(n^2)}{n^2}=\frac{\sigma(n)}{q^k}.$$ Then $$\frac{\sigma(q^k)}{n}\cdot t\frac{\sigma(n)}{q^k}<2=\frac{\sigma(q^k)}{q^k}\cdot\frac{\sigma(n^2)}{n^2}=\frac{ \sigma(q^k)}{q^k}\cdot\frac{\sigma(n)}{q^k}$$ so that $q^k < n$. Additionally, $$\frac{\sigma(n^2)}{n^2}=\frac{\sigma(n)}{q^k}$$ implies that $${q^k}\sigma(n^2) = {n^2}\sigma(n).$$ Therefore, $n^2 \mid {q^k}\sigma(n^2)$ and $q^k \mid {n^2}\sigma(n)$. Since $\gcd(q,n)=\gcd(q^k, n^2)=1$, then $n^2 \mid \sigma(n^2)$ and $q^k \mid \sigma(n)$. This implies that $$\frac{\sigma(n^2)}{n^2}=\frac{\sigma(n)}{q^k}$$ is an integer, contradicting $$1 < \frac{\sigma(n^2)}{n^2} < 2.$$ (In fact, we have the stronger bound $8/5 < \sigma(n^2)/n^2$.) Consequently, $$\frac{\sigma(n^2)}{n^2} \neq \frac{\sigma(n)}{q^k}.$$ Therefore, we either have $$\frac{\sigma(n)}{q^k} < \frac{\sigma(n^2)}{n^2} < 2$$ or $$\frac{8}{5} < \frac{\sigma(n^2)}{n^2} < \frac{\sigma(n)}{q^k}.$$ The second case implies $q^k < n$ since $$\frac{\sigma(n)}{n} < \frac{\sigma(n^2)}{n^2} < \frac{\sigma(n)}{q^k}.$$ The first case implies $$n <

{2^{\frac{\ln(12/13)}{\ln(9/13)}}}\cdot{(q^k)^{(\frac{\ln(13/12)}{\ln(13/9)}+\ln(13/9))}} \approx (1.162854)\cdot(q^k)^{0.5853949291}$$ if we use the estimate $$\frac{\sigma(n^2)}{n^2} < \bigg(\frac{\sigma(n)}{n}\bigg)^{\frac{\ln(13/9)}{\ln(4/3)}}.$$ Note that the inequality $$n < {2^{\frac{\ln(12/13)}{\ln(9/13)}}}\cdot{(q^k)^{(\frac{\ln(13/12)}{\ln(13/9)}+\ln(13/9))}} \approx (1.162854)\cdot(q^k)^{0.5853949291}$$ almost violates the inequality $q^k < n^2$. References The Abundancy Index of Divisors of Odd Perfect Numbers The Abundancy Index of Divisors of Odd Perfect Numbers - Part II

How to prove that $p_{n+1}p_{n+2}p_{n+3}>p_{n+4}p_{n+5}$?

p_n is the n-th prime number: If $n > 3$ then: $$p_{n + 1} p_{n + 2} p_{n + 3} > p_{n + 4} p_{n + 5}$$ I checked the conjecture above true for first fifty million primes. If the conjecture above is true, it is stronger than Bonse's inequality. Could you give your remark, reference, or your proof of conjecture above?

Length of curve $X_2(t) = (t\cos t, t\sin t)$ where $(0 \le t \le 2\pi)$

Here I got $X_2(t) = (t\cos t, t\sin t)$ where $(0 \le t \le 2\pi)$ Let $X_2(t) = (x, y)$ then $x^2 + y^2 = t^2 \;\;\forall t\in[0, 2\pi]$ now will divide $[0,2\pi]$ into $n-identical$ segments. then we get $[0, \frac{2\pi}{n},2\frac{2\pi}{n},..k\frac{2\pi}{n}, (k+1)\frac{2\pi}{n},...n\frac{2\pi}{n}]$ then we take kth and $(k+1)th$ term, and measure the distance between two: $d(X_2(k\frac{2\pi}{n}),X_2((k+1)\frac{2\pi}{n})) = \sqrt{[k\frac{2\pi}{n}\cos k\frac{2\pi}{n}-(k+1)\frac{2\pi}{n}\cos((k+1)\frac{2\pi}{n})]^2+[k\frac{2\pi}{n}\sin k\frac{2\pi}{n}-(k+1)\frac{2\pi}{n}\sin((k+1)\frac{2\pi}{n})]^2}=\sqrt{k^2(\frac{2\pi}{n})^2+(k+1)^2(\frac{2\pi}{n})^2-2k(k+1)(\frac{2\pi}{n})^2[\cos k\frac{2\pi}{n}\cos (k+1)\frac{2\pi}{n}+\sin k\frac{2\pi}{n}\sin (k+1)\frac{2\pi}{n}]} $ then if we let $n\rightarrow \infty$, we can estimate that $[\cos k\frac{2\pi}{n}\cos (k+1)\frac{2\pi}{n}+\sin k\frac{2\pi}{n}\sin (k+1)\frac{2\pi}{n}] \rightarrow 1$ thus $d(X_2(k\frac{2\pi}{n}),X_2((k+1)\frac{2\pi}{n})) \rightarrow \frac{2\pi}{n}$ thus, total length would be $\frac{2\pi}{n}\cdot n = 2\pi$ I had developed my own conjecture as denoted above, and wants to be verified and get some correction for illogical reasoning. Any harsh ones are welcomed.

Conjectured formula for the standard Clausen function

I often guess generalizations based on subtle patterns. I found the following formula in such a way and I wonder how it can be proven. Let n be a non-negative integer. Then \begin{align} \text{Cl}_{n}(x)&=(-1)^{\lfloor\frac{n-1}{2}\rfloor}x^{n-1}\left(\frac{H_{n-1}-\ln x}{\Gamma(n)}+\sum_{k=1}^{\lfloor\frac{n-1}{2}\rfloor}(-1)^k\frac{\zeta(2k+1)}{x^{2k}\Gamma(n-2k)}+2\sum_{k=1}^\infty\frac{\zeta(2k)\Gamma(2k)}{\Gamma(n+2k)}\left(\frac{x}{2\pi}\right)^{2k}\right) \\&=(-1)^{\lfloor\frac{n-1}{2}\rfloor}\left(\psi^{(-n)}(x)-\psi^{(-n)}(x+1)+\sum_{k=1}^{\lfloor\frac{n-1}{2}\rfloor}(-1)^k\frac{x^{n-2k-1}\zeta(2k+1)}{\Gamma(n-2k)}+2\sum_{k=1}^\infty\frac{x^{n+2k-1}\zeta(2k)\Gamma(2k)}{(2\pi)^{2k}\Gamma(n+2k)}\right) \end{align} where $\text{Cl}_{n}(x)$ is one of the standard Clausen functions defined by $$ \text{Cl}_{n}(x)= \begin{cases} \sum_{k=1}^\infty\frac{\sin(kx)}{k^n}& n\space\text{even}\\\\ \sum_{k=1}^\infty\frac{\cos(kx)}{k^n}& n\space\text{odd} \end{cases} $$ Edit: Upon further investigation, the proof can likely be derived from equations 2.7 and 2.8 of this paper.

A conjecture about primes

Conjecture: For each prime p there are an infinite number of primes q such that $p+q$ is a perfect square. I have done a lot of tests using Bigz and I believe that it's possible to prove. I change from possible to prove to not possible to disprove. Define for all primes q, $w_q(n)=|\{p\in\mathbb P|p<n\wedge \exists k\in\mathbb N:p+q=k^2\}|$. Then I've observed that it seems that for all primes q there exists a natural number N and a $\alpha\in\mathbb R_+$ such that $m>N$ implies that $w_q(10^m)>\alpha2^m$. This would imply the conjecture and is maybe possible to disprove.

Primes + Inetvel + conjecture on primes

a) Can we establish a proof, there exists infinitely many primes of the form n^2 + 1. Why is the unit digit of such a prime p always 1 or 7? Is there any reasonable procedure or concept for the fact that the unit digit 7 occur essentially twice as often, when we identify the primes < 10000? b) can we prove or disprove that, there exists an interval of the form [n^2, $(n+1)^2$] containing at least 1000 prime numbers. c) We know that even integer > or = 4 can be written as sum of two primes and integers > 5 can be written as sum of three primes. Of course, those are conjectures. I am not asking the proof of those conjectures. I would like to know those statements are equivalent or not. If yes, how you will justify?

A $3n-2$ Conjecture for the Redheffer Matrix.

The divisor matrix $D=(d_{i,j})_{i,j\in\mathbb{N}}$ is defined by \begin{equation*} d_{i,j}=\begin{cases}1,\quad \text{if i divides j,}\\ 0\quad \text{otherwise.}\end{cases} \end{equation*} A finite truncation of the divisor matrix obtained from the upper left $n\times n$ submatrix of D, setting each entry in the first column to 1 was first studied by Raymond Redheffer. For our purpose we denote such matrices by $D[n]$ and eponomously refer to them as Redheffer matrices. Question: Can we show that $\text{tr}\left(D[n]^{2}\right)=3n-2$ For example, if $n=3$ then $$ D[3]=\begin{pmatrix} 1 & 1 & 1\\ 1 & 1 & 0 \\ 1 & 0 & 1 \\ \end{pmatrix}.$$ If we denote by $p(X)$ the characteristic polynomial of $D[3]$, then its zeros are given by the cubical equation, $ -X^3+3X^2-X-1=0. $ This equation has roots: $1, 1+\sqrt{2}$ and $1-\sqrt{2}$. The eigenvalues of $D[3]$ are precisely the roots of $p(X).$ We can check that $$ 3\cdot 3-2=7=1+(1+\sqrt{2})^2+(1-\sqrt{2})^2. $$

If $N=q^k n^2$ is an odd perfect number and $q = k$, why does this bound not imply $q > 5$?

Let $\mathbb{N}$ denote the set of natural numbers (i.e., positive integers). A number $N \in \mathbb{N}$ is said to be perfect if $\sigma(N)=2N$, where $\sigma=\sigma_{1}$ is the classical sum of divisors. For example, $\sigma(6)=1+2+3+6=2\cdot{6}$, so that 6 is perfect. (Note that 6 is even.) Denote the abundancy index of $x \in \mathbb{N}$ as $I(x)=\sigma(x)/x$. Euler proved that an odd perfect number N, if any exists, must take the form $N=q^k n^2$, where q is prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Suppose that $k=q$. Since q is prime and $q \equiv 1 \pmod 4$, this implies that $k \geq 5$. (In particular, $k \neq 1$, so that the Descartes-Frenicle-Sorli conjecture is false in this case.) Using WolframAlpha, we get the upper bound $$I(q^k)=I(q^q)=\frac{q^{q+1}-1}{{q^q}(q-1)} \leq \frac{3906}{3125} = 1.24992$$ which corresponds to the lower bound $$I(n^2)=\frac{2}{I(q^k)} \geq \frac{3125}{1953} \approx 1.6001\ldots.$$ Consider the product $$\bigg(I(q^q) - \frac{3906}{3125}\bigg)\bigg(I(n^2) - \frac{3906}{3125}\bigg).$$ This product is nonpositive. Therefore, $$I(q^q)I(n^2) + \bigg(\frac{3906}{3125}\bigg)^2 \leq \frac{3906}{3125}\cdot\bigg(I(q^q) + I(n^2)\bigg).$$ Since $N=q^k n^2$ is perfect with $q=k$, then $I(q^k)I(n^2)=I(q^q)I(n^2)=2$, so that $$I(q^q) + I(n^2) \geq \frac{3906}{3125} + \frac{3125}{1953} = \frac{17394043}{6103125} \approx 2.850022406554\ldots.$$ But in the paper [Dris, 2012 (pages 4 to 5)], it is proved that $$I(q^k) + I(n^2) \leq \frac{3q^2 + 2q + 1}{q(q+1)} = 3 - \frac{q-1}{q(q+1)}$$ with equality occurring if and only if $k=1$. In our case, since $k = q \geq 5$, we obtain $$\frac{17394043}{6103125} \leq I(q^q) + I(n^2) = I(q^k) + I(n^2) < 3 - \frac{q-1}{q(q+1)}$$ which implies that $$q > \frac{3125}{781} \approx 4.00128\ldots.$$ Here is my question: Why does the bound $$I(q^q) + I(n^2) \geq \frac{3906}{3125} + \frac{3125}{1953} = \frac{17394043}{6103125} \approx 2.850022406554\ldots$$ not imply that $q > 5$? I am thinking along the lines that: (1) $57/20 < I(q^k) + I(n^2) < 3$ is best-possible. (2) Improving the upper bound 3 would result in a finite upper bound for the Euler prime q. (3) Therefore, improving the lower bound $57/20$ would result in a lower bound for q better than the currently known $q \geq 5$. REFERENCES If $N=q^k n^2$ is an odd perfect number, does $q \leq 97$ imply that $I(q^k)+I(n^2) \leq 2.99$?

How often does $D(n^2) = m^2$ happen, where $D(x)$ is the deficiency of x?

Let $\sigma=\sigma_{1}$ denote the classical sum of divisors. For instance, $\sigma(12) = 1 + 2 + 3 + 4 + 6 + 12 = 28$. Let $x \in \mathbb{N}$ ($\mathbb{N}$ is the set of natural numbers/positive integers). Denote the number $2x - \sigma(x)$ by $D(x)$. We call $D(x)$ the deficiency of x. Now, let $m, n \in \mathbb{N}$. Here is my question: How often does $D(n^2) = m^2$ happen, where $D(x)$ is the deficiency of x? MY ATTEMPT I note (from the OEIS sequence listing) that $D(n^2) = m^2$ holds when $$(m, n) = \left\{(1, 1), (1, 2), (1, 4), (1, 8), \ldots \right\}$$ So, $n=2^r$ for integers $r \geq 0$ is an infinite family of numbers satisfying $D(n^2) = m^2$ (in particular, $m = 1$). Are $n=2^r$ for $r \geq 0$ the only numbers for which $D(n^2) = m^2$?

Do there exist deficient-perfect square numbers whose deficiency is also a square (and not one)?

This is a follow-up to this MSE question: How often does $D(n^2) = m^2$ happen, where $D(x)$ is the deficiency of x? Here is my question in this post: Do there exist examples for which $D(n^2) = m^2$ and $m \mid n$, where $m, n \in \mathbb{N}$ and $m > 1$? MY ATTEMPT In the linked MSE question, the following examples for $D(n^2) = m^2$ (without the divisibility constraint) were given: $$(m_1, n_1) = (19, 46), m_1 \nmid n_1$$ $$(m_2, n_2) = (53, 284), m_2 \nmid n_2$$ $$(m_3, n_3) = (3509, 149728), m_3 \nmid n_3$$ $$(m_4, n_4) = (6479, 242656), m_4 \nmid n_4$$ $$(m_5, n_5) = (1583, 1633), m_5 \nmid n_5$$ $$(m_6, n_6) = (223309, 260495), m_6 \nmid n_6$$ Rephrasing my question a bit, I have: Do there exist deficient-perfect square numbers whose deficiency is also a square (and not one)? Added on July 09 2017 I have the following bounds for $D(n^2)/n^2$ in terms of an auxiliary variable q: $$\frac{2}{q+1} \leq \frac{D(n^2)}{n^2} < \frac{2}{q}.$$ The conditions specified in my problem imply that $$\frac{2}{q+1} = \frac{m^2}{n^2}.$$ Added on July 12 2017 - MOTIVATION When $N=q^k n^2$ is an odd perfect number, then the following equations hold: $$\gcd\left(n^2,\sigma(n^2)\right)=\frac{D(n^2)}{\sigma(q^{k-1})}=\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}.$$ (This is proved in this preprint, to appear in NNTDM.) In particular, when the Descartes-Frenicle-Sorli conjecture that $k=\nu_{q}(N)=1$ is true, then $D(n^2) \mid n^2$. In the other direction, Broughan, et. al (page 7, Lemma 8) proved that if $$\frac{\sigma(N/q^k)}{q^k}=\frac{\sigma(n^2)}{q^k}$$ is a square, then $k=1$.

Putting these all together, under the assumption that $\sigma(n^2)/q^k$ is a square, we have that $$1 < m^2 = D(n^2) \mid n^2.$$ Now, MSE user Matthew Conroy checked all $n < {10}^7$ and found only one ODD deficient-perfect square (other than 1), namely $n^2 = {3003}^2 = 9018009$, with deficiency 819. (Notice that the deficiency is not a square.) All other deficient-perfect squares are powers of 2, up to $n < {10}^7$. Indeed, if $n = 2^k$ for some integer $k \geq 0$, then n^2 is deficient-perfect with deficiency 1.

Area of enclosed smooth curve is always irrational for rational dimensions

I have the intuition that smooth curves that are enclosed cannot be possible in real world , so it must be the case that either the dimensions(parameters) that define the curve (like the radius of circle) are irrational or for real dimensions the area of the curve is irrational like for example for circle () and ellipse (). Is there any such proof (for or against) for this conjecture for generic smooth enclosed curve ?.

Fibonacci conjecture: $(F_{n+5})^2 - (F_n)^2 = 3((F_{n+3})^2 - (F_{n+2})^2) + 8 F_{n+2} F_{n+3} $.

So this is the question I have The Fibonacci sequence is a recurrence system given by $$F_1 = 1, \ F_2 = 1, \ F_{n+2} = F_{n+1} + F_n \qquad (n = 1, 2, 3, \ldots).$$ This question concerns the following conjecture: $$(F_{n+5})^2 - (F_n)^2 = 3((F_{n+3})^2 - (F_{n+2})^2) + 8 F_{n+2} F_{n+3} \qquad (n = 1, 2, 3, \ldots).$$ (a) Confirm that the conjecture is true when $n = 6$. (b) Prove that the conjecture is true for all integers $n \geq 1$. But when I go through the solution I don't understand one line (separated and marked). (b) Let n be any integer such that $n \geq 1$. $$\begin{align} \left(F_{n+5} \right)^2 - \left(F_n \right)^2 &= \left(F_{n+5} - F_n \right) \left(F_{n+5} + F_n \right) \\ &= \left(F_{n+4} + F_{n+3} - F_{n+2} + F_{n+1} \right) \left(F_{n+4} + F_{n+3} + F_{n+2} - F_{n+1} \right) \\ \\ &= \left(\color{red}{2} F_{n+3} + F_{n+1} \right) \left(2 F_{n+3} + 2 F_{n+2} - F_{n+1} \right) \tag{*} \\ \\ &= \left(2 F_{n+3} - F_{n+3} - F_{n+2} \right) \left(2 F_{n+3} + 2 F_{n+2} - F_{n+3} + F_{n+2} \right) \\ &= \left(3 F_{n+3} - F_{n+2} \right) \left(F_{n+3} + 3 F_{n+2} \right) \\ &= 3 \left(\left(F_{n+3} \right)^2 - \left(F_{n+2} \right)^2 \right) + 8 F_{n+2} F_{n+3} \end{align}$$ Hence, the conjecture is true for all integers $n \geq 1$ In the marked line, where does the red $\color{red}{2}$ come from?

Parity-dependent pth-powers conjecture

For $p\in\mathbb{N}$ a monic polynomial q_p exists with $S_p(n):=\sum_{k=1}^nk^p=\frac{n(n+1)}{p+1}q_p(n)$. After $q_1=1$ we seem to have an alternating pattern, with $$q_2=n+\frac{1}{2},\\q_3=n(n+1),\\q_4=(n^2+n-\frac{1}{3})q_2,\\q_5=(n^2+n-\frac{1}{2})q_3,\\q_6=(n^4+2n^3-n+\frac{1}{3})q_2,\\q_7=(n^4+2n^3-\frac{1}{3}n^2=\frac{4}{3}n+\frac{2}{3})q_3,\\q_8=(n^6+3n^5+n^4-3n^3-\frac{1}{5}n^5+\frac{9}{5}n-\frac{3}{5})q_2,\\q_9=(n^2+n-1)(n^4+2n^3-\frac{1}{2}n^2-\frac{3}{2}n+\frac{3}{2})q_3.$$In particular we have the following conjectures: For $k\ge 1$ degree-($2k-2$) monic polynomials $A_k,\,B_k$ exist for which $q_{2k}=q_2A_k,\,q_{2k+1}=q_3B_k$ so that S_{2k} has repeated roots $-1,\,0$ and S_{2k+1} has roots including $-1,\,-\frac{1}{2},\,0$; For $k\ge 2$ the polynomials $A_k,\,B_k$ have the same next-to-leading coefficients. Can we prove, or at least make some sense of, any of these results? It feels like the $-\frac{1}{2}$ root and the repeated roots have some interpretation, and the fact that A_k-B_k is of degree $\le 2k-4$, should have some significance.

conjectured continued fraction related to certain polynomials

Let n be any complex number and q be a real number such that $q\in\Big(-\frac{1}{4};\frac{1}{4}\Big)$,$n\in\Big(-\infty;\infty\Big)$,it is then conjectured that the following is true $$G(q,n)=\cfrac{1}{1-q+\cfrac{q(1-q)^n}{1-q^3+\cfrac{q(1-q^3)^n}{1-q^5+\cfrac{q(1-q^5)^n}{1-q^7+\cfrac{q(1-q^7)^n}{1-q^9+\ddots}}}}}\\=1+(n+1)\frac{q^2}{1!}-(n^2+n+4)\frac{q^3}{2!}+(n^3+6n^2+23n+30)\frac{q^4}{3!}-(n^4+22n^3+71n^2+218n+384)\frac{q^5}{4!}+(n^5+65n^4+265n^3+1315n^2+3634n+6000)\frac{q^6}{5!}-(n^6+171n^5+1225n^4+6765n^3+24334n^2+70464n+118080)\frac{q^7}{6!}+(n^7+420n^6+5908n^5+33810n^4+159859n^3+595770n^2+1638552n+2766960)\frac{q^8}{7!}-(n^8+988n^7+27146n^6+179200n^5+1057049n^4+4580212n^3+16233244n^2+44611440n+75519360)\frac{q^9}{8!}+ \dots$$ Special cases ($n=-1$) $$\cfrac{1}{1-q+\cfrac{\frac{q}{\Big(1-q\Big)}}{1-q^3+\cfrac{\frac{q}{\Big(1-q^3\Big)}}{1-q^5+\cfrac{\frac{q}{\Big(1-q^5\Big)}}{1-q^7+\ddots}}}}=1-2q^3+2q^4-9q^5+29q^6-92q^7+316q^8-\dots$$ ($n=i$) $$\cfrac{1}{1-q+\cfrac{q(1-q)^i}{1-q^3+\cfrac{q(1-q^3)^i}{1-q^5+\cfrac{q(1-q^5)^i}{1-q^7+ \dots}}}}=1+\Big(1+i\Big)q^2-\Big(\frac{3}{2}+\frac{i}{2}\Big)q^3+\Big(4+\frac{11i}{3}\Big)q^4-\Big(\frac{157}{12}+\frac{49i}{6}\Big)q^5+\Big(\frac{475}{12}+\frac{337i}{12}\Big)q^6- \dots$$ where $i=\sqrt{-1}$ Note that by analysing the conjectured form it is evident that the coefficients of the series expansion are polynomial sequences. The form of the RHS suggests that the continued fraction is the exponential generating function $G(q)=\sum_{n=1}^{\infty}\frac{a_{n}}{n!}q^{n}$ for the given polynomials a_{n}(assuming we ignore matters of convergence). How do we prove that the conjecture is true? and if true,can it be related to some well established theory? PS:The radius of convergence had to be revised based on @mercio's argument supported by @Einar Rødland

k-tuple Admissibility?

Admissibility is defined for the integer k-tuples by the non-existence of a prime number p, for which each element of the k-tuple under union forms a complete residue system $\pmod{p}$. If we define $H \subset \mathbb{Z}$ as a k-tuple and $H' = (\mathbb{Z}/m\# \mathbb{Z})^\times$, the multiplicative group of residue classes with a primorial modulus, such that the modulus $m\#$ is greater than the diameter of H. Is it equivalent to say that if there exists a number $n \in \mathbb{Z}$, such that the translation on the number line $H \oplus n \subseteq H'$, that H is admissible?

Euler Totient of Numbers Between Twin Primes.

Are there any known special properties of a number located between twin primes? The question came up in the discussion. (The expression below has been rephrased to a weaker form for clarity) In studying admissibility of k-tuples I observed that $$\varphi(\lambda) \le \lim_{\lambda < n \le \infty} \inf \varphi(n) $$ where we use the set theoretical representation of a twin prime pair as $\{\lambda-1, \lambda+1\} \subset \mathbb{P}$ and the definition of $\lim \inf x_n$ is given by $\lim_{N\rightarrow \infty} \inf x_k: k \in [N, \infty]$, and I'm not quite sure how to prove the statement above on the totient of a "lumenal" (?) number beyond conjecture. I think amWhy is curious as well. This post may be related, because this is a special case of the same problem. Now, of course, with the explicit formula for Euler totient, $$ \varphi(n) = n \prod_{p|n} \bigg(1 - \frac{1}{p} \bigg) $$ we do, in fact, end up with $\frac{ \varphi(n)}{n}$ having the product form in terms of the prime divisors of n giving the value $n-1$ when $n \in \mathbb{P}$. If we were not prime, then there would be another factor less than one in the formula for totient. Similar logic applies for the number $n+1$, because $n+1$ cannot be prime and as a result $\varphi(n+1) < n$. But this doesn't entirely explain the conjectured expression. For context, we arrive at a similar expression for the totient of a prime number $$\varphi(p) > \sup_{0 < n < p} \varphi(n) $$

Number of monomials in $a_n=a_{n-1}+(a_{n-2})^2$ with $a_1=a$, $a_2=b$

I was playing around with the sequence $a_1=a$, $a_2=b$ and the recurrence $a_n=a_{n-1}+(a_{n-2})^2$ and just listed out a few general terms. For instance, $a_1=a$, $a_2=b$, $a_3=b+a^2$, $a_4=b+b^2+a^2$, $a_5=a^4+2a^2b+a^2+2b^2+b$, and $a_6=b^4+2b^3+3b^2+2a^2b^2+4a^2b+b+2a^4+a^2.$ When I did that, I realized that the number of terms in a_n appears to be F_n where F represents the Fibonacci numbers. I conjecture that this is true, but I am not sure how to even approach this.

Does the Rogers-Ramanujan continued fraction $R(q)$ satisfy this conjectured infinite series

Given the Rogers-Ramanujan continued fraction $R(q)= \cfrac{1}{1+\cfrac{q}{1+\cfrac{q^2}{1+\cfrac{q^3}{1+\ddots}}}}$ where $q=\exp(2\pi i \tau)$, $|q|\lt1$ for the sake of brevity, let us introduce the following notation $R_{0}=\frac{1}{R(q)}$ $R_{1}=\frac{1}{\Big(\frac{1}{q}\Big(\frac{1}{R(q)}-1\Big)\Big)}$ $R_{2}=\frac{1}{\Big(\frac{1}{q^2}\Big(\frac{1}{\Big(\frac{1}{q}\Big(\frac{1}{R(q)}-1\Big)\Big)}-1\Big)\Big)}$ $R_{3}=\frac{1}{\Big(\frac{1}{q^3}\Big(\frac{1}{\Big(\frac{1}{q^2}\Big(\frac{1}{\Big(\frac{1}{q}\Big(\frac{1}{R(q)}-1\Big)\Big)}-1\Big)\Big)}-1\Big)\Big)}$ up to R_{n}, $\frac{1}{R_{n}}=R(q^n,q)$ for natural number n, where $R(a,q)$ is the Generalized Rogers-Ramanujan continued fraction as pointed out by @ccorn It is then conjectured that the following infinite series holds $\displaystyle -\frac{R'(q)}{R(q)}=\frac{1}{R_{0}R_{1}}-\frac{2q^2}{R_{0}R^2_{1}R_{2}}+\frac{3q^5}{R_{0}R^2_{1}R^2_{2}R_{3}}-\frac{4q^9}{R_{0}R^2_{1}R^2_{2}R^2_{3}R_{4}}+\frac{5q^{14}}{R_{0}R^2_{1}R^2_{2}R^2_{3}R^2_{4}R_{5}}-\dots\tag1$ It has the ascending continued fraction equivalent $\displaystyle -\frac{R'(q)}{R(q)}= \frac{\frac{1}{R_1}+\large{\frac{\frac{-2q^2}{R_2}+\large{\frac{\frac{3q^5}{R_3}+...}{R^2_2}}}{R^2_1}}}{R_0} \tag2$ After considering the Rogers-Ramanujan continued fraction with the factor $q^{1/5}$ and applying the identity $\frac{R'(q)}{R(q)}=\frac{1}{5q}\frac{(q;q)^5_{\infty}}{(q^5;q^5)_{\infty}}$ due to Ramanujan,we are led to the following beautiful identity $\displaystyle \frac{(q)^5_{\infty}}{(q^5)_{\infty}}=1-\frac{5q}{(R_{0}R_{1})}+\frac{10q^3}{(R_{0}R_{1})(R_{1}R_{2})}-\frac{15q^6}{(R_{0}R_{1})(R_{1}R_{2})(R_{2}R_{3})}+\frac{20q^{10}}{(R_{0}R_{1})(R_{1}R_{2})(R_{2}R_{3})(R_{3}R_{4})}-\frac{25q^{15}}{(R_{0}R_{1})(R_{1}R_{2})(R_{2}R_{3})(R_{3}R_{4})(R_{4}R_{5})}+\dots\tag3$ $\displaystyle \frac{(q)^5_{\infty}}{(q^5)_{\infty}}=1+5\sum_{n=1}^{\infty}\frac{(-1)^n nq^{\frac{n(n+1)}{2}}}{\prod_{k=1}^{n-1}\Big(R_{k}+q^k\Big)}$ Question:How do we prove that the conjecture is true? Remark As entry 9 in chapter 19 of Ramanujan's second notebook we have the ff well known identity $\displaystyle \frac{(q)^5_{\infty}}{(q^5)_{\infty}}=1-5\sum_{n=1}^{\infty}\left(\frac{n}{5}\right) \frac{n q^n}{1-q^n}\tag{4}$ Combining (1) and Ramanujan's identity (4), we are immediately led to $\displaystyle \sum_{n=1}^{\infty}\left(\frac{n}{5}\right) \frac{n q^n}{1-q^n}=\sum_{n=1}^{\infty}\frac{(-1)^{n-1} nq^{\frac{n(n+1)}{2}}}{\prod_{k=1}^{n-1}\Big(R_{k}+q^k\Big)}\tag{5}$

Conjecture about distribution of certain primes

Conjecture: Let $f(x,y,z)=xy+xz+yz\:$ and $\: S_m=\{n\in\mathbb N|n<m\wedge f(p_n,p_{n+1},p_{n+2})\in\mathbb P\}$. Then $|S_m|\sim \frac{m}{\ln m}$. Computationally tested only, but I would like to see a proof. It seems like I made a mistake with the inequality in the comment, but here are some data: m m/ln m |Sm| pi(m) li m |Tm| 10 4.34 5 4 6.1655995 6 100 21.71 26 25 30.1261416 41 1000 144.76 171 168 177.6096580 295 10000 1085.74 1292 1229 1246.1372159 2234 100000 8685.89 10102 9592 9629.8090011 12024 1000000 72382.41 82114 78794 78627.5491595 5000000 324150.19 366716 348513 348638.1150413 For comparision: $T_m=\{n\in\mathbb N|n<m\wedge f(a_n,a_{n+1},a_{n+2})\in\mathbb P\}$, where $a_n=2n+1$

How can we prove that $F_p \in \mathcal {P} \lor Φ?$

I have created a conjecture which I do not know how to prove. The conjecture is written like: $F_p \in \mathcal {P} \lor Φ$ p = prime number in correspondence to the appearance of a number in the Fibonacci Sequence. $\mathcal {P}$ = The set of prime numbers in the Fibonnaci Sequence. $Φ$ = The set of Fibonacci numbers that have $1+$ divisors which cannot be divided into any earlier Fibonacci numbers. My conjecture, is that if you have a prime-th Fibonacci number, then that number is either going to be prime or have factors of which are not factors of any earlier Fibonacci numbers. Here is a list of the first 10 Fibonacci numbers. 1) 1 2) 1 3) 2 4) 3 5) 5 6) 8 7) 13 8) 21 9) 34 10) 55 As we can see, all prime-th Fibonacci numbers in the list $\in$ $\mathcal {P}$ except for the 2^{nd} Fibonacci number because 1 is not considered a prime, but we will consider it a prime to all numbers. Now as we list the following 20 Fibonacci numbers this time, we will start to notice that not all prime-th Fibonacci numbers are prime. The 19^{th} Fibonacci number is 4181 which is not a prime number. $4181 = 37 \times 113$ $\therefore$ $4181 \in Φ$ $\because$ it's factors $(37, 113)$ are not factors of any Fibonacci number before 19. All prime-th Fibonacci numbers after 4181 are prime, but then when we come across the 31^{st} Fibonacci number being 1346269, which is also not a prime number. $1346269 = 557 \times 2417$ $\therefore$ $134629 \in Φ$ $\because$ it's factors $(557, 2417)$ are not factors of any Fibonacci number before 1346269. The most common factor I assume to be divided into fibonnaci numbers is 2^3 where I assume that $2^3 | F_{6 + 12n} : n \in \mathbb{W}$. Now at first you would believe that $α(F_p \in \mathcal {P}) > α(F_p \in Φ)$: $α(χ) =$ amount of times $χ$ appears. But as $P_y \rightarrow \infty$ the gap between $(F_p \in \mathcal {P})_y \land (F_p \in \mathcal {P})_{y + 1} \rightarrow \infty$ at a much faster rate the greater the value of y : $y \in \mathbb{Z^+}$ $\therefore$ $α(F_p \in \mathcal {P}) < α(F_p \in Φ)$ the greater the value of y, and when $y > 137$ then $α(F_p \in \mathcal {P}) \ll α(F_p \in Φ)$. $φ$ can be expressed as a limit: $$\lim_{k \rightarrow \infty} \frac{F_k + 1}{F_k} = φ : k \in \mathbb{Z^+}$$ $\because$ $F_k = F_{k + 1} - F_{k - 1}$ (you can carry out the mathematics from there). However even if I substitute k as p, and then substitute F_p with their unique prime factorisation $\iff$ $F_p \in Φ$, it does not get me anywhere. Is there a way to prove that this conjecture works either via this approach or another? The largest Fibonnaci prime I know in the sequence so far is $F_{9311}, (9311 = prime)$ so if that is a key fact to finding a proof, please provide it in your answer if you have one. It would be much appreciated. If you do not know what any of the various symbols in this question mean, I will post an edit to this question tomorrow to explain their definition which will be when I see your answers $-$ I have to go to sleep now. G'night.

How is moving the last digit of a number to the front and multiplying related to multiplicative orders?

There seems to be a relationship between multiplicative orders modulo n and a puzzle Presh Talwalkar gave a few days ago at https://www.youtube.com/watch?v=1lHDCAIsyb8 I'm hoping someone can give a more rigorous explanation of the pattern I see. $\bullet\textbf{ The Puzzle }\bullet$ He states the puzzle as: "What Positive Number Doubles When Its Last Digit Becomes Its First Digit?" For example, the smallest solution - assuming base-10 representation - is 105263157894736842. Which means that $$(2)\cdot105263157894736842 \quad\ \ \ $$ $$||$$ $$2105263157894736842$$ Naturally, one can proceede to find solutions in other bases. The base-5 solution is $$(2)\cdot102342_5 \quad\ \ \ $$ $$||$$ $$210234_5$$ $\bullet\textbf{ Multiplicative Order Connection }\bullet$ The base-10 solutions is 18 digits and the base-5 solution is 6 digits. I wrote a program to generate the smallest solution in all bases and then counted the number of digits in each such solution. Here's the sequence, starting with base-2 $$2,4,3,6,10,12,4,8,18,6,11,20,...$$ $$\uparrow \quad\quad\quad\quad\ \uparrow \quad\quad$$ $$\text{Base-} 5 \quad\quad\quad \text{Base-} 10 \quad\quad$$ A quick search on http://oeis.org/ shows that these numbers are the multiplicative order of $$2\ (\text{mod } 2B-1)$$ where B is the representation base we are working in. See http://oeis.org/A002326 This puzzle can be further generalized by finding numbers that triple instead of double upon moving the last digit to the front. Let's introduce an arbitrary multiplying factor: k So the solutions mentioned above and Talwalkar's puzzle are a particular case when $k=2$ For a different example, let's look at $k=5$ in base-7. The smallest solution is $$(5) \cdot 1013042156536245_7 \quad\ \ \ $$ $$||$$ $$5101304215653624_7$$ This solution is 16 digits long. As we did before for base-10, we can write out a sequence of the number of digits in each base's solution starting with base-2 $$6,6,9,2,14,16,4,5,42,18,...$$ $$\uparrow\ \ $$ $$\text{Base-}7\ \ $$ Another search on http://oeis.org/ quickly shows that these numbers are the multiplicative order of $$5\ (\text{mod } 5\cdot7-1)\quad\text{or rather}\quad 5\ (\text{mod }34)$$ $\bullet\textbf{ A Conjecture }\bullet$ The pattern might be clear now. After checking other cases, it seems that the smallest positive number in any base B - which is k times the value gotten by moving it's last digit to the front - has a number of digits equal to the multiplicative order of $$k\ (\text{mod } Bk-1)$$ I can see how multiplicative order would be related to this problem. But I can't find an exact reason why this relationship should be so. Is there an intuitive reason?

Does anyone know the name of this conjecture?

Given p and q are two different prime numbers. Does there exist a positive integer n such that $p^n = 1 \pmod q$ Is this conjecture true? If so, any source of the prove. What is the name of this conjecture or theorem (if it is true)?

If N is a sum of two squares, then so is the odd part of N

Given two natural numbers m,n, where m is odd. Please prove that if $m\cdot2^n$ is a sum of two squares, then m is a sum of two squares. Tested for all $m\cdot2^n<100,000$. I love the natural numbers but feels number theory being inapproachable. So I'm experimenting and mostly (mis)use ME as a "proof calculator". While testing and using my BigZ I analyze sets and sequences of numbers like below. 1 1000 ~ :| n | n sqrsum ; intcond \ create all square sums in intervall function odd-part transform-set \ transform to odd parts zdup cardinality . 153 condition sqrsum filter-set \ only square sums filter zdup cardinality . 153 \ conclude the conjecture in the question condition noprime filter-set \ remove all primes from the set condition nosqr filter-set \ remove all squares set-of-factors \ create the set of all prime factor-tuples cr zet. \ and print it: {(5,197),(3,3,109),(5,193),(13,73),(5,5,37),(3,3,101),(5,181),(17,53),(3,3,97),(5,173),(5,13,13),(7,7,17),(3,3,89),(13,61),(5,157),(3,3,5,17),(5,149),(5,5,29),(17,41),(13,53),(5,137),(3,3,73),(7,7,13),(17,37),(5,11,11),(3,3,5,13),(5,113),(3,3,61),(5,109),(13,41),(5,101),(17,29),(5,97),(13,37),(3,3,53),(5,89),(5,5,17),(3,3,3,3,5),(13,29),(3,3,41),(5,73),(3,3,37),(5,5,13),(5,61),(5,53),(3,3,29),(5,7,7),(13,17),(5,41),(5,37),(3,3,17),(5,29),(5,5,5),(3,3,13),(5,17),(5,13),(3,3,5)} ok From the remaining set the Sum of Two Squares Theorem is almost visible. Also see my blog about using the most low level high level language Forth for mathematical calculations with sets and big integers.

A conjecture inspired by a famous contest problem

There is a famous difficult problem: For all natural numbers a,b it's true that: $\displaystyle(ab+1)|(a^2+b^2)\implies \frac{a^2+b^2}{ab+1}$ is a perfect square. I've noticed $(a=1,\dots 100)$ that for each a there's a b such that $(ab+1)|(a^2+b^2)$ and my question is if this can be proved generally? Induction seems to lead nowhere.

What must the value of y be so that a and b are integers?

I have made some sort of conjecture that in the equation: $$a^2 = b^2 + 2y^2.$$ y must equal $(2n + 1)\sqrt {8}$ such that $n \in \mathbb{W}$ for a and b to be integers, or at least Pythagorean Triples. All I believe that is most correct is that for every value of n there are at least four solutions to satisfy the equation. And that for some other integer x, if $a^2 = x + y$ and $b^2 = x - y$ then this will work out, but it doesn't seem to be that $x + y$ and $x - y$ can both be squared numbers $\in \mathbb{W}$. Could somebody please help me prove/disprove this? I am a little bit stuck. Thanks.

Prime clasfication by some constructive function

How to prove or justify the following: $$ f(g)= \frac1{1-g^2} \prod_{k=1}^{\infty} \left(\frac{\sin(\pi \frac gk)}{\pi \frac gk} \cdot \frac 1{1-\frac{g^2}{k^2}}\right). $$ The above statement can illustrate the following facts: (1) if $f(g) = 0$, then g is composite number (2) If $f(g)$ is not equal to 0, the g is prime number (3) if $f(1+g) = 0$, then g is prime. Please justify.

Any odd number is of form $a+b$ where a^2+b^2 is prime

This conjecture is tested for all odd natural numbers less than 10^8: If $n>1$ is an odd natural number, then there are natural numbers a,b such that $n=a+b$ and $a^2+b^2\in\mathbb P$. $\mathbb P$ is the set of prime numbers. I wish help with counterexamples, heuristics or a proof. Addendum: As in Greg Martins answer $$k(n)\approx k'(n)=\frac{3}{4}\frac{n}{\ln n} \displaystyle \prod_{\substack{p\equiv1\pmod 4 \\ p\mid n}} \frac{p-1} {p-2}\prod_{\substack{p\equiv3\pmod 4 \\ p\mid n}} \frac {p-1}p$$ which gives the diagram where k is the blue curve and k' is the red curve.

A conjecture about an unlimited path

Conjecture: For all primes of the form a^2+b^2, there are natural numbers s,t,u,v such that $\quad s^2+t^2,u^2+v^2$ are primes $\quad a+b=s+t$ $\quad u+v=s+t+2$ $\quad |s-u|+|t-v|=2$ This conjecture implies Any odd number is of form $a+b$ where a^2+b^2 is prime and seems to be much stronger. I have tested it for $a+b<50.000$ without founding a counterexample, but I guess there may exist counterexamples. In the diagram the vertices correspond to points (x,y) where x^2+y^2 is prime, the red edges correspond to pairs of vertices with taxi cab distance equal to 2 and the gray diagonal lines is the (taxi cab) equidistance lines to origin. The conjecture says there are paths following red edges and gray diagonal lines up to any distance from origin. Addendum: Further tests show that there exists red vertical edges that together with the gray diagonal lines make such paths for all odd $n=a+b=3,\dots,49,999$ except for $n\in\{9,19,49,75,149\}$. In this case I want help with finding counterexamples.

Hard for-all-integer-problems proveable for very great integer limits

Computational experiments suggests the conjecture: All big enough odd numbers N is of the form $N=\sum_{k=1}^n m_k$, where $\sum_{k=1}^n m_k^2$ is prime and all $m_k\in\mathbb Z^+$. Since the possible combinations of partitions of N increase with increasing N and n, the case with $n=2$ is tested for $N<10^8$ and seems to be supported by heuristics, and the cases $n=3,4,5$ are tested for N up to 200, I'm interested to understand the following, which is my question: Are there reasons to believe that a proof for some "big" n with N "big enough" would be within reach while proofs for "small" n isn't, at the moment?

Conjectures (or intuitions) that turned out wrong in an interesting or useful way

The question What seemingly innocuous results in mathematics require advanced proofs? prompts me to ask about conjectures or, less formally, beliefs or intuitions, that turned out wrong in interesting or useful ways. I have several in mind, but will provide just one here now, as an example. For centuries mathematicians tried to show that Euclid's parallel postulate followed from his others. When Lobachevsky, Bolyai and Gauss discovered that you could do interesting geometry just as consistent as Euclid when the parallel postulate failed a whole new world was open for exploration. One example per answer, please. If you want to post several, answer repeatedly. Related: Conjectures that have been disproved with extremely large counterexamples?

Any integer is of the form $n=a_1^2+a_2^2+a_3^2-a_4^2-a_5^2$

I've struggled with this conjecture, which probably can be proved: Any natural number n can be written as $n=a_1^2+a_2^2+a_3^2-a_4^2-a_5^2$ for some $a_1,a_2,a_3,a_4,a_5\in\mathbb Z^+$. I guess there are some polynomials $a_k=p_k(n)$ that solves the problem by substitution. But which? I'm almost sure that ME can prove the conjecture.

Most even numbers is a sum $a+b+c+d$ where $a^2+b^2+c^2=d^2$

I have no idea how hard this conjecture is to prove: Any even number $n\ge 36$ can be written as $n=a+b+c+d$ where $a^2+b^2+c^2=d^2$ and $a,b,c,d\in\mathbb Z^+$. Small exceptions are $n=2, 4, 6, 10, 12, 14, 20, 26, 34.\,$ Tested for $n\le 10,000$. A counter-example would be as interesting as a proof. n as above must be even $d-c,c+d|a^2+b^2$

A characteristic property of soluble groups

In the paper A characteristic property of soluble groups, P. Hall proved that in a finite soluble group, if one has elements $a,b,c,\ldots$ of coprime orders, and you suppose that $abc\ldots=1$, then actually $$a=b=c=\ldots=1$$ He conjecture that this statement is actually equivalent to the property of being soluble. Is this result already been established? If so, where I can find it?

If $q^k n^2$ is an odd perfect number with Euler prime q, does $\sigma(n^2)/q^k < q$ hold?

If $q^k n^2$ is an odd perfect number with Euler prime q, then it is known that $$\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}=\frac{D(n^2)}{\sigma(q^{k-1})}=\gcd\left(n^2,\sigma(n^2)\right),$$ where $\sigma(x)$ is the sum of divisors of $x \in \mathbb{N}$ and $D(x)=2x-\sigma(x)$. (See this paper for a proof.) Here is my question: Does $\sigma(n^2)/q^k < q$ hold? MY ATTEMPT It is easy to prove that $\sigma(n^2)/q^k \neq q$. For suppose to the contrary that $$q=\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}.$$ This means that $$2n^2 = q\sigma(q^k)$$ which implies that $q \mid n^2$, contradicting $\gcd(q,n)=1$. So now, assume that $\sigma(n^2)/q^k > q$. We obtain $$\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}=\frac{D(n^2)}{\sigma(q^{k-1})}=\gcd\left(n^2,\sigma(n^2)\right)>q,$$ from which we get $$2n^2 > \sigma(n^2) > q^{k+1}$$ $$2n^2 > q\sigma(q^k)$$ $$2n^2 - \sigma(n^2) > q\sigma(q^{k-1}) \geq q$$ $$\gcd(n^2, \sigma(n^2)) > q,$$ whence I do not arrive at a contradiction.

conjectured relations of mock theta functions of order 3

Given the following mock theta functions of order 3,found in this wikipedia article $f(q)=\sum_{n=0}^{\infty} \frac{q^{n^2}}{(-q;q)^2_{n}}$,$\phi(q)=\sum_{n=0}^{\infty} \frac{q^{n^2}}{(-q^2;q^2)_{n}}$,$\omega(q)=\sum_{n=0}^{\infty} \frac{q^{2n(n+1)}}{(q;q^2)^2_{n+1}}$ and $\nu(q)=\sum_{n=0}^{\infty} \frac{q^{n(n+1)}}{(-q;q^2)_{n+1}}$ where $q=e^{2\pi i\tau}$,$|q|\lt1$ and $(a;q)_n=\prod_{j=0}^{n-1}(1-aq^j)$ I propose the conjecture that the following relations hold $\Big(\phi(q)-1\Big)^2+\Big(f(q^2)-1\Big)=2\sum_{k=1}^{\infty}\Big(\sum_{n=1}^{\infty} \frac{q^{(n-1)^2+2k(n-1)+2k^2}}{(-q^2;q^2)_{k} (-q^2;q^2)_{n+k-1}}\Big)\tag1$ and $\Big(\nu(q)-\frac{1}{(1+q)}\Big)^2+\Big(\omega(-q)-\frac{1}{(1+q)^2}\Big)=2\sum_{k=1}^{\infty}\Big(\sum_{n=1}^{\infty} \frac{q^{n^2+(2k-1)n+2k^2}}{(-q;q^2)_{k+1} (-q;q^2)_{n+k}}\Big)\tag2$ How do we prove the conjecture? Note:comparing coefficients on the RHS and LHS of (1) and (2) respectively,we observe that the coefficients are equal and the identities are both special cases of the more general identity $\Big(\sum_{n=1}^{\infty} \frac{x^n z^{n^2}}{(a;q)_{n}}\Big)^2+\sum_{n=1}^{\infty} \Big(\frac{x^n z^{n^2}}{(a;q)_{n}}\Big)^2=2\sum_{k=1}^{\infty}\Big(\sum_{n=1}^{\infty} \frac{x^{n+2k-1} z^{(n-1)^2+2k(n-1)+2k^2}}{(a;q)_{k} (a;q)_{n+k-1}}\Big)\tag3$ with complex number x and z,$z\lt1$whereby a transformation($(a;q)_n\rightarrow (a;q)_{n+c}$ or $(a;q)_n\rightarrow (a;q)_{cn}$) on the LHS results in an equivalent transformation($(a;q)_k\rightarrow (a;q)_{k+c}$ or $(a;q)_k\rightarrow (a;q)_{ck}$) on the RHS for natural number c

When does the Ext-quiver of a finite-dimensional algebra have no oriented cycles, or what structure does it have?

Let H be a finite-dimensional algebra and $S(1), \dots, S(n)$ be the simple modules of H. Let Q be the Ext-quiver of H, i.e. Q has as vertices the simple modules $S(1), \dots, S(n)$ and an arrow $S(i) \to S(j)$ provided Ext$^1_H(S(i), S(j)) \neq 0$. Question: What is known or conjectured about the question when there cannot be an oriented cycle in the Ext-quiver? The no loop conjecture (which is, as far as I know, only proven for algebraically closed fields, see for example A proof of the strong no loop conjecture by Igusa, Liu and Paquette) says that in finite global dimension there cannot be a loop in the Ext-quiver. Is there an analogous statement or conjecture for oriented cycles? I'm also interested in references, if you know any. Added later: As pointed out by Stephen, there cannot be a general analogous statement. Nevertheless, I'm additionally interested in anything you know about the structure of the Ext-quiver whenever H has finite global dimension, whether it is related to cycles or not.

The set of primes of the form a^2+8b^2, where $a,b\in\mathbb N_+$

Due to the Brahmagupta identity the product of numbers of the form a^2+nb^2, with a fixed n, is on the same form. For $a,b,n\in\mathbb N_+$, these semigroups B_n are generated bye sets of primes G_n of the same form. It's well known that $G_1=\mathbb P\setminus(4\mathbb N+3)$ and easy to see that $G_4=\mathbb P\cap(4\mathbb N+1)$. My computations suggest that $G_8=\mathbb P\cap(8\mathbb N+1)$. I would like a proof or a counterexample? Sorry about the errors in the first editions. It's OK to redraw the votes.

How to guess a formula

"The 'proof by induction' works well provided that we think we know the formula in advance. In other words, it is a good technique to transform a Conjecture in a Theorem." Biggs, N. L., Discrete Mathematics, ch. 4.4. Sometime, creating the proper Conjecture is on our shoulder. But, what is the criteria? What elements should I keep considered in order to develop a formula? E.g. Guess a formula for the sum $\sum_{r = 1}^n(br + c),$ where b and c are given numbers, and prove it by using the principle of induction. First, I tried to make a table: $n:\qquad 1\qquad\qquad 2\qquad\qquad 3\qquad\qquad 4\qquad\qquad 5 $ $S_n:\quad 1b+c\quad 3b + 2c\quad 6b + 3c\quad10b + 4c\quad 15b + 5c $ but I failed to transform this pattern in an usable formula. The solution reports $\frac{1}{2}bn^2 + (\frac{1}{2}b + c)n$. Which steps should I follow to get from the table I created to the correct formula? Apart from this specific case I reported as an example, is there a general method? Are there criteria? Guides? Is it mainly based on intuition and personal creativity and knowledge?

Has this conjecture been discovered before? (Concerns prime numbers and not $\#(n)$ like in a question similar to this)

This is my second question today (I want to keep my major questions seperate): Let's denote the n^{th} prime number as p_n. Given the equation: $$\frac{p_1p_2p_3 \cdots p_n}{1 + p_1 + p_2 + p_3 + \cdots + p_n} = \{x_m : x_m \in\mathbb{Z}^+\}$$ Now the LHS is

not always equal to a positive integer, but when it is, it is equal to x_m. The first positive integer it will be equal to (which is 1) is denoted as x_1 such that $m = 1$ and $n = 2$, and the second integer (which is 715) is denoted as x_2 such that $m = 2$ and $n = 6$ etc. Conjecture: $$δ(x_m) = \{2^{2m - 1} : m > 1 \ \land \ δ(x_m) = \text{number of divisors of x_m including x_m itself}\}$$ $$m > 1 \because δ(x_1) = δ(1) = 1 \neq 2^{2\times 1 - 1} = 2$$ Is there a way to prove/disprove this? This is my own conjecture and I put my own little symbols to it. Could somebody please explain to me why this works and any examples where it doesn't (if they exist)? If this is somebody else's conjecture then I will delete this post. I am in Year 9, so my skill level in mathematics is not too high (compared to most users on this site), so I am sure somebody else must have discovered this. Thanks to this site, the only non-Year 9 maths I am familiar with include: Sets Matrices Sum/product series Σ and Π Imaginary (lateral) numbers $\sqrt{\text{negative}}$ (not particularly complex numbers $a + bi$) Quadratic equations Logarithms $\log_bn = m$ Trigonometry ΔABC and Linear Graphs $y = mx + c$. I guess these are the only things that may make you wonder if I actually am in Year 9. Everything else that what a Year 9 is usually taught, I also know. If you are using other techniques and ways of proving/disproving my conjecture, please be clear and try not to skip too many steps. I have not decided to name my conjecture as of yet (and I don't want to be selfish by naming it based on my own name) but I want to see what you think of it. Thank you in advance.

some property of the simple continued fraction for the riemann-zeta function

Define the well known Riemann-zeta function $$\zeta(n)=\sum_{k=1}^{\infty}\frac{1}{k^n}$$ for natural number $n\gt1$ and let $a_1(n)$ be a sequence $a_1(1),a_1(2),a_1(3),\dots$ of the first partial quotients of the simple continued fraction for $\zeta(2n+1)$, $$\zeta(2n+1)=\{a_0(n);a_1(n),a_2(n),a_3(n),a_4(n),a_5(n),\dots\}$$ The sequence $a_0(n)=1$, and the other sequence $a_1(n)$ increases with n,while the rest of the sequence of partial quotients $a_2(n),a_3(n),a_4(n),\dots$ seem to be random How do we prove that $\lim_{n\rightarrow\infty} \frac{a_1(n)}{a_1(n+1)}=\frac{1}{4}$ Example $\zeta(151)=\{1;2854495385411919762116571931558091627803291516,1,4,1,1,\dots\},$ see wolframalpha and $\zeta(153)=\{1;1141798154164767904846628774254547461112916991 5,7,1,15,1,\dots\},$ see wolframalpha then $$\frac{a_1(75)}{a_1(76)}=\frac{2854495385411919762116571931558091627803291516}{1141798154164767904846628774254547461112916991 5}=0.249999999999999999999999999996428\dots$$

Does a counterexample always disprove a conjecture?

I'm sincerely confused on this topic (the title). I was wondering if a counterexample always disproved a conjecture. I'm leaning towards true because it's not really a counterexample if it evaluates to false... right? Any insight or help would be dearly appreciated.

A question about Brown Numbers $(m, n) : n! + 1 = m^2$

So I recently looked at a video on YouTube by Numberphile which is accessible down below: Brown Numbers $-$ Numberphile The video was about so-called numbers called Brown Numbers. These types of numbers are a pair of integers (m, n) such that $$n! + 1 = m^2$$ When you have a term looking a little like this $\longrightarrow n!$ it is not read as shouting the term before the exclamation mark (and the term before the exclamation mark isn't called the coefficient either). It is read as, in this case, n factorial and is equal to the product of every number from 1 to n including n itself. $$n! = 1\times 2\times 3\times \cdots \times n = \prod_{k = 1}^{n}k$$ Understanding what $n!$ means, we can now find a

pair of Brown Numbers to substitute for m and n in the equation, however in the video, it was revealed that only three pairs of Brown Numbers have been found, and it has been conjectured that there only exists three pairs of Brown Numbers. $$\begin{align} (5, 4) \qquad 4! + 1 &= 1\times 2\times 3\times 4 + 1 = 24 + 1 = 25 = 5^2 \\ (11, 5) \qquad 5! + 1 &= 1\times 2\times 3\times 4\times 5 + 1 = 120 + 1 = 121 = 11^2 \\ (71, 7) \qquad 7! + 1 &= 1\times 2\times 3\times 4\times 5\times 6\times 7 + 1 = 5040 + 1 = 5041 = 71^2 \end{align}$$ It was also revealed in the video that this conjecture has not been proven, so I accepted the challenge of proving it, but came across a problem. My Attempt: If $$n! + 1 = m^2$$ then $$n! = m^2 - 1 = m^2 - 1^2 = (m + 1)(m - 1)$$ Assume that $m = 2r$ for some integer r. $$n! = (2r + 1)(2r - 1) = (2r)^2 - 1^2 = 4r^2 - 1$$ $$\implies n! + 1 = 4r^2$$ We arrive at a contradiction. Since $n! = 1\times 2\times \cdots \times n$ then if $n > 1$, n is even. Any even number plus 1 is an odd number, and an even number cannot divide an odd number, thus 4 does not divide an odd number, so m cannot be even. Now let $m = 2r \pm 1$. $$n! = (2r \pm 1 + 1)(2r \pm 1 - 1) = (2r \pm 2)(2r) = 2(r \pm 1)(2r) = 4r(r \pm 1)$$ We now arrive at another contradiction. 4 now divides m, but 4 is even and m is odd! (This attempt can serve as a Lemma to proving that for any integer x, if x is even/odd, then x^y is even/odd.) Did I do something wrong? I must have. Besides, every Brown Number so far is odd and not even.

Feedback on a general conjecture for A = Bp - Cq where p and q are primes?

I previously asked for feedback on the following conjectures (similar in appearance to Goldbach ‘s and Lemoine’s see: Two new conjectures related to Lemoine's and Goldbach's) : $O = 2n + 1 = p - 2q$ always has a solution in distinct odd primes p and q for $O \ge 5$ $O = 2n + 1 = 2q - p$ always has a solution in p and q with $q < p$, p being an odd prime and q being 1 or an odd prime and $O \ge 1$ Those two conjectures, even though they do not seem easy to prove, are very weak: the number of possible solutions is possibly infinite. (Since increases in p and q have opposite effect.) Also, while it is possible by concrete calculations to increase the domain of proven validity, it is not possible to find a concrete counter example since a solution may lay with higher values of p and q. Since they are so easy to satisfy, I thought that they may become more interesting if they were generalized by changing the component $2q$ into $2nq$. It is easy to see that in $O = p-2nq$ we will not have solutions in primes p and q as long as n and O have common divisors. So the revised conjectures become: For O, odd natural number, and n ,natural number ,without common divisors: $O = p - 2nq$ always has a solution in distinct odd primes p and q for $o \ge 5$ $O = 2nq - p$ always has a solution in p and q with $q < p$, p being an odd prime and q being 1 or an odd prime and $o \ge 1$ I verified that it is the case for all $O < 2000000$ and $n < 1000$ But better, a further generalization is possible that envelops these conjectures: $A = Bp - Cq$ where the natural numbers A,B,C have no common divisor and one of them is even has solutions in p and q odd primes or 1 I verified this with values of A, B and C ranging from 1 to 1000.

Is every number a sum of 3 tetrahedral numbers?

It is known that every number can be represented by a sum of 3 triangular numbers. According to Gauss (see formula 35 in mathworld article) $$ \text{num}=\Delta+\Delta+\Delta $$ I did some numerical experiments that suggest the above formula is correct when triangular numbers are replaced by tetrahedral numbers $$ \Delta=\frac{n(n+1)(n+2)}6 $$ if n is allowed to be negative. Is this conjecture correct? I tried to google representation of integers by tetrahedral numbers but didn't find anything.

About three conjectures concerning the Pythagorean Theorem.

I have two main conjectures relating to the Pythagorean Theorem that I desperately want to find out if they are true or not. Could somebody please help me? If $ \ a^2 + b^2 = c^2 \ $ for which c is a prime number, then for some $n \in \mathbb{N}, \ c = 4n + 1$. $\forall \{x, y, z\} \subset \mathbb{N}, \ \big(x^2 + (x + 1)^2\big)^2 = y^2 + z^2 \ $ for which $x \neq y \neq z$. Tested for $c, x \leqslant 10^6$. I did also have another conjecture that if $ \ a^2 + b^2 = c^2 \ $ for which a is odd (and greater than 1), b is even, and $a < b$ then there existed a solution such that $c = b + 1$, but I am 100% certain this has been discovered before (assuming so, since it was not very difficult to notice). However I am not sure if the other two conjectures have been discovered before, although if it had to be one of them, I would pick the second one. So could somebody also please clarify that for me? Thank you in advance.

Conjectured continued fraction for the Jacobi theta function $\vartheta_{4}(q)$

Given the Jacobi theta function $$\vartheta_{4}(q)=1+2\sum_{n=1}^{\infty}(-1)^nq^{n^2}$$ where $q=e^{2\pi i\tau}$, and $|q|\lt1$. It is conjectured that it has the following continued fraction $\vartheta_{4}(q)=1-\cfrac{2q}{1-q+\cfrac{q}{1-\cfrac{q^2}{1-q^3+\cfrac{q^2}{1-\cfrac{q^3}{1-q^5+\cfrac{q^3}{1-\cfrac{q^{4}}{1-q^7+\cfrac{q^{4}}{1-\dots}}}}}}}}\tag{1a}$ and its reciprocal, $\begin{aligned}\frac{1}{\vartheta_{4}(q)}=1+\cfrac{2q}{1-q-\cfrac{q}{1+\cfrac{q^2}{1-q^3-\cfrac{q^2}{1+\cfrac{q^3}{1-q^5-\cfrac{q^3}{1+\cfrac{q^{4}}{1-q^7-\cfrac{q^{4}}{1+\dots}}}}}}}}\end{aligned}\tag{1b}$ How do we prove the conjecture? Edited later: If we define the q-pochhammer symbol for any complex number a, $$(a;q)_{\infty}=\prod^{\infty}_{n=0}\left(1-aq^n\right) $$ the conjectured continued fractions can be generalized to the following form $\begin{aligned}\prod_{n=0}^\infty\frac{\big(1-aq^n\big)}{\big(1+aq^n\big)}=1-\cfrac{2a}{1-q+\cfrac{a}{1-\cfrac{aq}{1-q^3+\cfrac{aq}{1-\cfrac{aq^2}{1-q^5+\cfrac{aq^2}{1-\cfrac{aq^{3}}{1-q^7+\cfrac{aq^{3}}{1-\dots}}}}}}}}\end{aligned}\tag{1c}$ which obviously leads to the continued fraction for the reciprocal of $\vartheta_{4}(q)$ when $a\rightarrow -q$.

Conjecture: $a^3 + b^3 + c^3 = p^3 \Rightarrow x^3 + y^3 + z^3 = \big(\frac{a + b + c}{2}\big)^3$

Conjecture: Let p be an even perfect number, and a, b, c be positive natural numbers. There exists values for a, b, c to satisfy the following equation $$a^3 + b^3 + c^3 = p^3$$ for which $\bigg(\dfrac{a + b + c}{2}\bigg)^3 = x^3 + y^3 + z^3$ for natural numbers x, y, z. Tested for all perfect numbers up to $2^{30}(2^{31} - 1) = 2305843008139952128$. I posted something similar relating to this a while ago on the Math Overflow and now I need better computer-power. Ideally, I want a better way to approach this problem in order to prove/disprove this, but I do not know how or where to begin. Could somebody please help me? Also, this is just a speculation, but every prime number can be written of the form $a^3 - b^3 - c^3$ for some natural a, b, c. This includes 2, but there is already a formula for 2: $$2 = (6t^3 + 1)^3 - (6t^3 - 1)^3 - (6t^2)^3$$ Also, if you have the following equation: $$\qquad \ \ \ a^3 + b^3 + c^3 = \big\{d^3 : \min\{a, b, c\} = 6\big\}$$ $$\implies 6 \mid d + (-1)^{n + 1}$$ for which $a^3 + b^3 + c^3 = d^3$ is the n^{th} equation such that $\min\{a, b, c\} = 6$. Thank you in advance. Edit: Here is the link to my post on the $MO \longrightarrow$ About prime numbers and the sum of three cubes And here are a few examples of a, b, c, x, y, z as part of the conjecture in the yellow box: Let $a = 3, b = 4, c = 5$ then $x = 3, y = 4, z = 5$. Let $a = 18, b = 19, c = 21$ then $x = 11, y = 15, z = 27$. Let $a = 57, b = 82, c = 495$ then $x = 15, y = 213, z = 281$ or $x = 162, y = 173, z = 282$. Let $a = 2979, b = 4005, c = 7642$, this was too high for me to calculate a while ago so I went here to find the value of $\big((a + b + c)/2\big)^3$ which I did, being equal to 7313, meaning that 7313^3 can be written as the sum of three positive cubes.

The fractal dimension of the Kolakoski sequence is $2-1/e$

The Kolakoski sequence, which is defined as the infinite sequence of symbols {1,2} that is its own run-length encoding (Wikipedia), has been suggested to be self-similar^{1}. The fractral dimension of a self-similar time-series is directly related to its Hurst exponent^{2}. I have estimated the Hurst exponent of the Kolakoski sequence for different sequence lengths, and found that the answer converges near $1 / e$ when the sequence length increases. This suggests that the fractral dimension of the Kolakoski sequence is $D=2-H = 2-1/e.$ Here is a small subset of the data sequence length hurst exponent 1e2 .1167 1e3 .1796 1e4 .2236 1e5 .2579 1e6 .3108 1e7 .3464 1e8 .3657 2e8 .3720 3e8 .3766 My question is: Can you find a proof for this conjecture? If yes, I would be interested to write a brief note about this to a mathematical journal. References: ^{1} https://maths-people.anu.edu.au/~brent/pd/Kolakoski-ACCMCC.pdf ^{2} https://en.wikipedia.org/wiki/Hurst_exponent#Relation_to_Fractal_Dimension

A conjecture concerning numbers of the form $k\sqrt{2}$ where $k \in \mathbb{N}$

I was experimenting with radicals on my calculator when I noticed that the units digit and the hundredths digit of $\sqrt{2}, \, 2\sqrt{2}, \, ... \, 11\sqrt{2} \,$ are the same. The next one does not work since in $12\sqrt{2} = 16.97...$ ($6 \neq 7$). On doing this up to $50\sqrt{2}$, I found that the numbers $\alpha\sqrt{2}$ which don't work are when $\alpha = 12, 19, 24, 31, 36, 38, 41, 43, 48, 50$. My conjecture: The units digit and the hundredths digit of a number of the form $k\sqrt{2} \,$ ($k \in \mathbb{N}$) are the same, except when k is of the form $12a+19b+41c$ where $a, b, c \in \mathbb{Z^+} \cup \left \{0 \right \}$. Does anyone know how to prove this (or give a counterexample)? Also, if this is true, are there similar conjectures for numbers of the form $k\sqrt{3}, \, k\sqrt{5}, \, ...$? Thanks!

Repdigit Conjecture

I noted a conjecture down a while back after doing a fair few calculations on repdigits and noticing patterns. Define some digit repetition syntax for a 'string of integers' x and an integer y, let $x;y$ be x repeated and concatenated y times. For example $$ 123;3 = 123123123\\ 9;10 = 9999999999 $$ then it seemed that for all strings I have tried the following was true: For a prime b, if $\frac{s;a}{b}$ is an integer then $\frac{s;k}{b}$ is also an integer for any k such that $k \bmod (b-1) = a$ This is best shown with some examples, for $s=165$, $a=3$, $b=5$, $$ \frac{s;a}{b} = \frac{165165165}{5} = 33033033 \in \mathbb{Z}\\ \{k:k\bmod(b-1)=a\} = \{k:k\bmod 4 =3\} = \{3,7,11,\cdots\} $$ so we can predict that $$ \frac{165;7}{5}=\frac{16516516516516516565}{5} \in \mathbb{Z} \;\;(true)\\ \frac{165;11}{5}=\frac{165165165165165165165165165165}{5} \in \mathbb{Z} \;\;(true)\\ $$ and so on. Moreover, it seems we can concatenate (denoted by the $|$ symbol) some other strings around this pattern take for example \begin{equation} \frac{11222221}{97}= \frac{11|2;5|1}{97} \in \mathbb{Z} \end{equation} then we have $a=5,b=97,k=5,101,197,\cdots$ \begin{equation} \frac{11|2;101|1}{97} \in \mathbb{Z} \end{equation} (which appears to be true) This leads to a modified conjecture For a prime b and strings A and B, if $\frac{A|s;a|B}{b}$ is an integer then $\frac{A|s;k|B}{b}$ is also an integer for any k such that $k \bmod (b-1) = a$ This seems to work if the number is a repdigit in any integer base for example in binary $427=110101011_2=(11|01;3|1)_2$ we have $$ \frac{(11|01;3|1)_2}{7} = \frac{427}{7} = 61 \in \mathbb{Z}\\ k = \{3,9,15,\cdots\}\\ \frac{(11|01;9|1)_2}{7} = \frac{1747627}{7} \in \mathbb{Z} \\ \frac{(11|01;15|1)_2}{7} = \frac{7158278827}{7} \in \mathbb{Z} $$ This makes me suspect it is something to do with the pattern rather than the numeric content per se. Questions: Can the conjecture be proved true or false? Can a counter example be found? Why does this work/not work?

Can this summation be proved to equal 1 for any upper bound 0 or greater?

$$\sum_{i=0}^n \frac{(n-i+1)^n (-1)^i}{i!(n-i)!} =1$$ Prove that the summation above always equals 1 for any integer n greater than or equal to zero. I believe that it probably does equal one always. I've tested low numbers for n and used computers to get slightly higher values confirmed. The problem comes when the factorials and number of terms get to high for accurate computation. I'm looking for a way to prove it is true for all numbers that meet the integer and greater than zero stipulations. If there is a counter example, then that also works to disprove the statement. I'm guessing that simplification of the summation would be useful for a proof, but I've found it very difficult to create a more simplified summation than the one above. If you try out a few numbers, you'll notice that the way that the summation works out to be one is pretty cool.

On expressing a square as a sum of two cubes

Given $a,b,c \in \mathbb{N}$ which satisfy the following conditions: $a^3 + b^3 = c^2$ $ a \neq b$ =-=-=-=-=-=-=-=-=-=-=-=-=-= EDIT, Will Jagy: The conjecture is that, for a given $c,$ there are at most two distinct pairs (a,b) with $1 \leq a < b$ and $a^3 + b^3 = c^2.$ Note the example $77976^2=1026^3+1710^3=228^3+1824^3$ that Gerry found with exactly two pairs. =-=-=-=-=-=-=-=-=-=-=-=-=-= There are maximum 2 possible pairs of (a, b) which satisfy this conditions. I have verified it for $a, b \leq 200\,000$. Note: the situation when a and b just take each others value is discarded.

Confirmation of a conjecture: $3\mid (8n)^5 - k$

I have made a conjecture: $$\forall n\in \mathbb{N} \setminus \{6r : r \in \mathbb{N}\}, \ 3\mid (8n)^5 - k$$ Such that $k =$ a constant containing all the digits of $(8n)^5$ except for the last 3. The order of digits is unecessary. e.g. Let $n = 1$. $(8\times 1)^5 = 32768 \Rightarrow k_1 = 32\require{cancel}\cancel{768} \ \land \ k_2 = 23\cancel{768}$ $32768 - 32 = 32736 = 3\times 10912$ or $32768 - 23 = 32745 = 3\times 10915$ $\therefore 3\mid (8n)^5 - k_1, k_2$ I do not know how to prove/disprove it apart from using computer power and trying to find a counter-example, however this has been tested for all $n \leqslant 10^6$ and I have not found one. Could somebody please help me? Thank you in advance.

Infinitely many simultaneous palindromes in "exponentially close" number bases?

I've observed regular patterns that suggest that there are infinitely many numbers which are simultaneously palindromic in n number bases of form: $$ b_1,b_2,b_3,\dots,b_n={x^{y_1},x^{y_2},x^{y_3},\dots,x^{y_n}} $$ For every combination of natural numbers $(n,x,y_1,\dots,y_n)\in\mathbb N$ you can pick. Where of course, $x\ge2$, since we are observing integer number bases $b_n\ge2$. For one example, this conjecture implies that there are infinitely many numbers simultaneously palindromic in number bases $3,9,81$; Some examples for this example: 10 ,20 ,82 ,164 ,820 ,1640 ,6562 ,6643 ,6724 ,13124 ,13205 ,13286 ,65620 ,66430,... The 66430 is an example since it can be written as $10101010101_3=111111_9=AAA_{81}$ Are there similar, more/less powerful(general) claims made/proven somewhere? Is there anything that would suggest a way this can be proven? (or perhaps disproven/reduced to a less general statement?) It is worth noting that the patterns were observed for $n\le3$, and $n=4$ for smaller x,y variables, since bigger values are too hard to compute for more than couple examples using my python code. (And thus hard to see/confirm whether the pattern extends to larger n) I was observing the gaps between palindromes, and palindromes produced by this conjecture, to formalize the patterns for smaller and simpler cases of variable combinations. Simplest case (pattern) in context For simplest example, we can generate infinitely many such palindromes for $b_1=2,b_2=4$ case using $a(x)=$A007583 and $b(x)=$A001511 to predict the gaps with: $$ g(k,d) = \begin{cases} 2\cdot a(b(k)), & \text{$d=4t-1 \land b(k)>2$} \\ a(b(k)), & \text{otherwise} \end{cases} $$ (See g values in the output below) The k goes from 1 to $2^{\lfloor(d/4)\rfloor}$ where d is the number of digits of odd digit palindromic examples behind the generated gaps (in b_1 representation). There are finitely many examples (one for each k) per d digit palindromes for each d, but infinitely many as d tends to infinity - grows larger. For more clarity, each following row contains gaps produced by g function, between examples for this case of "$d :$" digits: (In other words, each "," represents a number palindromic in both bases 2 and 4, and the values between them are the number of "$d :$" digit palindromes that are only palindromic in base 2) 3 : 1 5 : 1 ,1 7 : 1 ,2 9 : 1 ,1 ,3 ,1 11 : 1 ,2 ,6 ,2 13 : 1 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,1 ,2731 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,683 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,10923 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,683 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,2731 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,683 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,171 ,1 ,3 ,1 ,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1

,11 ,1 ,3 ,1 ,43 ,1 ,3 ,1 ,11 ,1 ,3 ,1 By picking large enough d we can get as many examples as we want. All this is for the simplest case of bases $(2,4)$. Similar patterns in the observed gaps (between palindromic representations) seem to exist for other combinations of variables, but they get rarer in examples and less predictable as n grows. For every odd d there seem to always be examples for any x,y's for small n, but for larger n we start getting more and more (always periodic?) gaps in these sets (rows above) of d digit odd palindromic examples gaps. By these gaps in gaps, I mean that some rows start getting blank (no examples), but others still seem to follow in increasing number of examples (so far non blank rows seem to appear periodically).

Confirmation of Proof: If p is a perfect number, then $1 + 8p$ is a squared number.

I have created a hypothesis: $$\text{If } p \text{ is a perfect number, then } 1 + 8p \text{ is a squared number.}$$ Could anyone prove/disprove the above statement? I have no idea where to begin, and I discovered this by pure accident when trying to solve a quadratic equation. Edit: I believe that all odd numbers m squared can be expressed as the form $8n + 1$ for some $n \in \mathbb{N}$. $$\begin{align} 3^2 &= 9 = 8\times 1 + 1 \\ 5^2 &= 25 = 8\times 3 + 1 \\ 7^2 &= 49 = 8\times 6 + 1 \end{align}$$ Yes, it is obvious that n is also a triangular number $(1 + 2 + 3 + \cdots)$. Let $m = 2k + 1$, then one has the following: $$(2k + 1)^2 = 8n + 1$$ And $(2k + 1)^2 = 4k(k + 1) + 1$, so it follows, then, that: $$4k(k + 1) \require{cancel}\cancel{+1} = 8n \cancel{+1} \Rightarrow k(k + 1) = k^2 + k = 2n$$ And since the parity of $r \in \mathbb{N}$ remains the same for r^k for all $k \in \mathbb{N}$ then our proof stands valid.

Status of a conjecture about powers of 2

I recently saw a conjecture on a blog (http://blog.tanyakhovanova.com/?p=311) which the author refers to as the 86 conjecture. The conjecture claims that all powers of 2 greater than 2^{86} have a zero in their base 10 representation. At first glance this seems like a numerical curiosity, and I wasn't sure that this was an interesting or deep mathematical question. I wanted to ask the community if they knew of any existing work that deals with either this type of question or something similar. I tried searching for 86 conjecture on Google and didn't get anything useful.

Sequences $p,p+d,p+2d,\dots,p+N\cdot d$ of prime numbers

A conjecture that I believe is possible to prove: For any $N\in\mathbb N$ there is a $d\in\mathbb N$ such that $p,p+d,p+2d,\dots,p+N\cdot d$ all are primes (for some prime p). My context: it seems that greater $\omega(d)$ (number of different prime factors) gives greater N.

The difference of two coprime composites

I guess this is a simple task for them who know some number theory: Any natural number is the difference between two coprime composites. Tested up to 1000. I develop some computer tools to investigate sets and now and then find some patterns or connections that makes me formulate a conjecture, which in my mind just is a word for an unproved statement.

A conjecture for an inequality for every odd number.

Let $E(n) = \sum_{d|n} d \log(d) $. Then for coprime n,m we have $$E(mn) = \sigma(m) E(n) + \sigma(n) E(m).$$ Suppose there exists an odd perfect number n. Then$$E(2n) = E(2)\sigma(n)+E(n)\sigma(2) = 4 n \log(2) + 3 E(n).$$ But looking at a few numerical examples, one can see that the right hand side seems to be alway bigger than the left hand side. Consider the upper bound for logarithm:$$\log(x) \le x^s/s. \quad \forall s>0$$ Making use of this upper bound we can derive: $$E(2n) = 2 \sum_{d|n} d \log(2d) + E(n) \le 2 \sum_{d|n} \frac{(2d)^s}{s} + E(n). \quad \forall s > 0$$ Now the question is, how do we choose $s>0$ such that we have $$2 \sum_{d|n} \frac{(2d)^s}{s} + E(n) < 4 n \log(2) + 3 E(n).$$ My conjecture is, that it is always possible to choose one such $s>0$ such that the last inequality is valid.

Conjectured value of a difficult integral with Dedekind eta functions

In my research on quantum groups I have the following conjecture: \begin{equation} \int_0^\infty\frac{\eta (2 i x)^8}{\eta (i x)^2 \eta (4 i x)^2}\,dx\,{\stackrel?=}\,\frac{K(\tfrac{1}{\sqrt{2}})}{\pi}\tag{1} \end{equation} where \begin{equation} \eta(ix)=e^{-\frac{\pi x}{12}}\prod_{n=1}^\infty (1-e^{-2n\pi x}) \end{equation} is the Dedekind eta function and \begin{equation} K(\tfrac{1}{\sqrt{2}})=\frac{\Gamma^2(\tfrac14)}{4\sqrt{\pi}} \end{equation} is the

Elliptic integral singular value. This value has been guessed using Inverse symbolic calculator and then checked numerically to a high precision, but I do not have a proof. Question: Is (1) true?

Where is the flaw in my proof?

Possible proof of the conjecture that there always exists a prime between n^2 and $(n+1)^2$? Assume the statement is invalid. Therefore, for some $n \in \mathbb{N}$, there does not exist a prime that ranges from n^2 and $(n+1)^2$ exclusive. Let $\pi (x)$ denote the amount of prime numbers less than or equal to x, then we have that if $\pi ((n + 1)^2) - \pi (n^2) = k$, there exists k primes that range between n^2 and $(n + 1)^2$ exclusive. Therefore, by assuming the conjecture is false, we consider $k = 0$, which consequently gives us the following: $$\begin{align} \pi ((n + 1)^2) - \pi (n^2) &= 0 \\ \Leftrightarrow \pi ((n+1)^2) &= \pi (n^2). \end{align}$$ It is well known that $\pi (x) \approx \dfrac{x}{\ln x}$ so by order of substitution, $$\frac{n^2}{\ln n^2} \approx \frac{(n + 1)^2}{\ln (n + 1)^2}.$$ For some m, one can see that $\ln x^2 = m \Rightarrow e^m = x^2 \Rightarrow \sqrt {e^m} = e^{m/2} = x \Rightarrow \ln x = m/2$. Therefore, we conclude that $\ln x^2 = 2\ln x$. $$\begin{align} \therefore \frac{n^2}{2\ln n} &\approx \frac{(n + 1)^2}{2\ln (n + 1)} \\ \\ \Leftrightarrow \bigg(\frac n2\bigg)\bigg(\frac{n}{\ln n}\bigg) &\approx \bigg(\frac{n + 1}{2}\bigg)\bigg(\frac{n + 1}{\ln (n + 1)}\bigg) \\ \\ \Leftrightarrow \bigg(\frac n2\bigg)\pi (n) &\approx \bigg(\frac{n + 1}{2}\bigg)\pi (n + 1) \\ \\ \Leftrightarrow \frac{n}{n + 1} &\approx \frac{\pi (n + 1)}{\pi (n)}. \end{align}$$ Now, by taking the reciprocal of the equation, it follows then that, $$\frac{n + 1}{n } = 1 + \frac 1n \approx \frac{\pi (n)}{\pi (n + 1)}.$$ However, although true, $$\square \ \dfrac{n + 1}{n} > \dfrac{\pi (n)}{\pi (n + 1)}.$$ By definition of the function π, we have that $\pi (n) = \pi (n + 1)$ if and only if n and $n + 1$ are not prime and $\pi (n) < \pi (n + 1)$ if and only if $n + 1$ is prime, therefore $\pi (n) \leqslant \pi (n + 1)$. We thus arrive at the following conclusion: $$\begin{align} \frac{\pi (n)}{\pi (n + 1)} &\leqslant 1 \\ \\ \Leftrightarrow \frac{n + 1}{n} &> \frac{\pi (n)}{\pi (n + 1)} \\ \\ \Leftrightarrow \pi ((n + 1)^2) &> \pi (n^2) \\ \\ \Leftrightarrow \pi ((n + 1)^2) - \pi (n^2) &\geqslant 1 \\ \\ \therefore k &= 1. \end{align}$$ Thus, the conjecture is true.$\qquad\qquad\qquad

Constant related to $f(n) = f(n-1) + \frac{1}{n f(n-1)}$

Consider the sequence f : $$f(1) = 1$$ $$ f(n) = f(n-1) + \frac{1}{n f(n-1)}$$ Now we have for large n : $$ f(n) = \sqrt {2 \ln(n)} + \frac{1}{19} + C + eps(n) $$ Where C is a constant and $eps(n)$ Goes to 0 for large n. Main question : Is $C = 0 $? If not What is Its value and do we have a closed form ?? Second question : How does eps behave ? Do we have a closed form ?

What is the name of the conjecture related to what Matt Parker has called "The Square-Sum Problem"?

I read a book called Things to Make and Do in the Fourth Dimension, written by Australian mathe-matician and comedian, Matt Parker. In one part of the book, I remember him explaining about a conjecture such that for all $n\geqslant 89$, you can arrange the elements of the set $\{1, 2,\ldots,n\}$ in a certain way where each adjacent pair of elements sums to a squared number. For example, let $n = 17$. Al-though $17<89$, below is a good example to demonstrate what I mean: We have the set $\{1, 2, 3,\ldots, 17\}$ which can also be written as $\mathbb{N}_{\leqslant 17}$. How can we order each number in a certain way such that every adjacent pair of numbers in the ordered sequence add up to a squa-red number? Well, we order it like so: Let $S_{17} = [\ldots]$ be our sequence that orders the elements from $\{1, 2, 3,\ldots, 17\}$ in a certain way as mentioned in the foregoing then, $$S_{17} := \big[17, 8, 1, 15, 10, 6, 3, 13, 12, 4, 5, 11, 14, 2, 7, 9, 16\big].$$ Here, $17 + 8 = 5^2$, $8 + 1 = 3^2$, $1 + 15 = 4^2,\ldots$ The sequence in the sandbox above is a special case where it has 17 elements and begins with 17. Take the sequence S_{16} then this sequence ends with 16. In fact, it is exactly the same as S_{17} except it does not start from 17, but 8 instead. However, the sequence S_{18} does not exist, and there are many sequences with this property that do not exist. The conjecture is interesting because if true, it will prove that there are only finitely many sequences S_n that do not exist, also proving the contrapo-sitive. I did some research and it seems like this is true for $89\leqslant n \leqslant 300$ thus far, but I do not know the name of this conjecture. Does it even have a name? I also haven’t stumbled across any attempts of proving this conjecture. Can it be done? I guess that is two questions, then. Thank you in advance.

How large will the smallest counter-example probably be?

Here : Primes p of the form $10^{m}(2^{k}-1)+2^{k-1}-1$, where m is the number of decimal digits of $ 2^{k-1}$. it is conjectured that the number $$(2^k-1)\cdot 10^m+2^{k-1}-1$$ where m is the number of decimal digits of $2^{k-1}-1$ (See also the title), is never prime when it is of the form $7s+6$. Amazingly, primes with the other residues exists although the residue 6 occurs twice often than 1. Upto $k=131\ 000$, there is no counter-example, but probably a counter-example exists because the growth rate is roughly 4^k and 1 out of 9 $k's$ lead to a number of the form $7s+6$. How large will the smallest counterexample probably be ?

On integer sequences of the form $\sum_{n=1}^N (a(n))^2H_n^2,$ where H_n is the nth harmonic number: refute my conjecture and add yourself example

After I've read a problem posed by Édouard Lucas from the first paragraph of the biography from this Wikipedia's article I am trying to get different variations of this problem using number theoretic functions. After I did some experiments (I've calculated some terms using Wolfram Alpha online calculator) I posed a surprising conjecture. Conjecture. Here H_n denotes the nth harmonic number. For each integer $n\geq 1$, the integer $$\sum_{k=1}^n (k!)^2(H_k)^2\tag{1}$$ is a square-free integer (has no repeated primes in its factorization, see this Wikipedia; we get 1 as $n=1$). Question 1. Can you refute numerically my conjecture? Can you provide us some reasoning about if our sequence (1) has infinitely many terms being square-free integers? Many thanks. As you see I tried to get a variation of the problem posed by Lucas, since my proposal in the RHS of my problem is the sequence of square-free integers instead of the square numbers, and the terms of my finite series are the squares of the integers $k!\cdot H_k$. I tried more examples using number theoretic functions. With the purpose of making this post more interesting I ask to this commmunity about other possible variations, and in order to ask a concise question, I am going to limit the nature of the sequences that are terms in our summation, now the square of sequences of the form $$a(k)\cdot H_k,$$ where $a(k)$ is a sequence of rational numbers. The RHS of your statement/conjecture can be any sequence (I prefer some interesting sequence of figurate numbers, see this MathWorld). Question 2. Provide us yourself example of a conjecture or statement from a sequence $a(k)$ or rational numbers, such that for each $n>N$ (for a suitable positive integer in your proposal) N $$\sum_{k=1}^n (a(k)\cdot H_k)^2=\text{ a sequence of integers* }.\tag{2}$$ *I prefer figurate numbers, or famous sequences of integers like prime numbers... Many thanks.

On the conjecture that, for every n, $\lfloor e^{\frac{p_{n^2}\#}{p_{n^2 + 1}}}\rfloor $ is a square number.

I was playing around with numbers and I discovered that $$\left\lfloor e^{\frac{p_4\#}{p_5}}\right\rfloor=\left\lfloor e^{\frac{210}{11}}\right\rfloor =13981^2,$$ with floor function $\lfloor x \rfloor := \max\{m\in\mathbb{Z} : m\leqslant x\}$; $ \ p_n$ denotes the n^{th} prime number; $ \ $and primorial $$p_n\#_c := \prod_{i=1}^n (p_i + c).\tag{$p_n\#_0 = p_n\#$}$$ Furthermore, $$\left\lfloor e^{\frac{p_1\#}{p_2}}\right\rfloor = 1^2.$$ I then made a conjecture with very few support, that $$\left\lfloor e^{\frac{p_{n^2}\#}{p_{n^2 + 1}}}\right\rfloor \tag1$$ is always a square number, say $k_n^{\ \ 2}$. Does somebody have a big enough computer to find the value of $(k_n)_{n\geqslant3}$? Or can my conjecture be proven/disproven with a pen and paper? And perhaps, to support the potential of this not being a coincidence, every divisor of 13981 takes the form $(13981 - 10x)$ for some $x\geqslant 0$. Maybe if this conjecture is true, $k_n > 1$ has this certain property? Edit 1: With some computational power, I found that $k_3^{\ \ 2}$ has $\approx 176,000$ digits. It turned out, however, that I was wrong, and really, $k_3^{ \ \ 2}$ has $\approx 3,340,970$ digits. Edit 2: Expressions equivalent to (1), avoiding e, for any base $b\in\mathbb{N}_{>1}$:$$\left\lfloor b^{\frac{p_{n^2}\#}{p_{n^2 + 1} \cdot Ln(b)}}\right\rfloor=k_n^{ \ \ 2}$$E.g. base $b=2$:$$\left\lfloor 2^{\frac{p_{n^2}\#}{p_{n^2 + 1} \cdot Ln(2)}}\right\rfloor=k_n^{ \ \ 2}$$E.g. base $b=n^2$:$$\left\lfloor (n^2)^{\frac{p_{n^2}\#}{p_{n^2 + 1} \cdot Ln(n^2)}}\right\rfloor=k_n^{ \ \ 2}$$

A conjecture concerning primes and perhaps prime gaps

I found out this conjecture which is tested for $m\leq 100$: For all natural numbers $n>\!30$, for all $\alpha\in\mathbb Z$ and all $\mu=0,\pm 1,\pm 2$: $m\equiv p_n^2+\mu p_n+\alpha\!\pmod{p_{n+1}}$ $\wedge\; m<p_{n+1}\iff$ $\exists k\in\mathbb Z_+:m=4k^2-2\mu k +\alpha$ Since this is a more general case than in the question For prime numbers p_n it holds $m\equiv p_n^2\pmod {p_{n+1}}\implies$ m is a square and that (due to an answer) was related to an unproved conjecture about prime gaps, I suspect that this conjecture is also related to prime gaps and is to deep to be proved. I would like to know: Can this conjecture relate to prime gaps? Are there counterexamples? Do someone have an intuition about the logic structure of the conjecture? Some context: I use bigz implemented in ANS-Forth with numbers and sets on stacks and all operations post-fix. First the case with $\alpha=\mu=0$: 1 100 :| n | n pnr@ ^2 n 1+ pnr@ umod dup sqr and ; build-set cr z. {0,1,4,16,36,64,100,144,196,324} ok DUP SQR AND mask the result from UMOD so all non square results are transformed to 0. SQR results in -1 or 0 depending on if the top of the number stack is a perfect square or not. Z. prints (and consumes) the set of the top of the set stack. 30 1000 :| n | n pnr@ ^2 n 1+ pnr@ umod dup sqr and ; build-set cr z. {0,4,16,36,64,100,144,196,256,324,400,484,576,676,784,900,1024,1156} ok Still exceptions indicated by 0 when $n\geq 30$. 31 1000 :| n | n pnr@ ^2 n 1+ pnr@ umod dup sqr and ; build-set cr z. {4,16,36,64,100,144,196,256,324,400,484,576,676,784,900,1024,1156} ok No exceptions when $n>31$. 31 10000 :| n | n pnr@ ^2 n 1+ pnr@ umod dup sqr and ; build-set cr z. {4,16,36,64,100,144,196,256,324,400,484,576,676,784,900,1024,1156,1296,1444,1600,1764,1936,2116,2304,2500,2704,2916,3136,3364,3600,3844,4096,5184} ok 31 50000 :| n | n pnr@ ^2 n 1+ pnr@ umod dup sqr and ; build-set cr z. {4,16,36,64,100,144,196,256,324,400,484,576,676,784,900,1024,1156,1296,1444,1600,1764,1936,2116,2304,2500,2704,2916,3136,3364,3600,3844,4096,4356,4624,4900,5184,5476,5776,6084,6400,6724,7056,7396,7744,8100,9216,9604,10000,12544,12996} ok The unbroken sequence of $4k^2$ values get longer for greater intervalls. Is this function prime infinitely often?

Is it provable that there exist infinitely many primes of the form, $$f(n) = \left\{-1 + (p_{n+2} - 1)\prod_{i=2}^np_i : (p_n)_{n\in\mathbb{N}} = n^{\text{th}}\text{ prime number.}\right\}?$$ This is prime for $n\in\{1,2,3,4,6,7,8,12,13,15,21,48\}$. I have checked for $n\leqslant 54$. The reason I want to know if there is inf many, is because I conjecture that for every counter-example which we can call $c_1, c_2, c_3,\ldots$ then $\Omega(c_k) \leqslant 4$ such that we denote by $\Omega(c_k)$ the number of prime factors of c_k for which the function does not count the same prime factor twice. For instance, $\Omega(64) = 1$ because $64 = 2^6 = 2\times 2\times 2\times\cdots \times 2$, and since 2 is prime, we only count it once, so the function in this case is equal to 1 (and not 6). Is there a way to prove/disprove my conjecture? If there are infinitely many primes $f(n)$ then perhaps I could apply that to proving my conjecture. Thanks in advance.

On a conjecture and other numbers like 144.

Yesterday, I noticed that the following numbers were prime: $$67, 167, 467, 967, 1667.$$ I realised that the digits of these primes, apart from 67, were square numbers: $$0^2, 1^2, 2^2, 3^2, 4^2.$$ I then wanted to find values a_n such that when we concatenate $a_n^{\ \ 2}$ with 67, it is a prime number. This means, we join $a_n^{\ \ 2}$ with 67 to form a new number, and we will denote this as $a_n^{\ \ 2}\mid\mid67$. For example, 1 concatenated with 2 is denoted as $1\mid\mid 2$ which equals 12. Below is a sequence of all the values a_n that range from 0 to 160 inclusive: $0,1,2,3,4,7,9,10,15,16,18,23,24,28,30,31,33,42,43,45,48,53,55,61,65,68,69,72,76,77,87,88,93,94,96,98,105,106,109,110,112,113,116,117,119,122,125,130,132,133,138,140,144,145,147,151,155,159.$ Here, $a_1 = 0$, $a_2 = 1$, $a_3 = 2$, $\ldots$ Conjecture 1. I made a conjecture that for every number $b_n^{\ \ 2}\mid\mid 67$ that is not prime, it will either have 2 or 3 divisors such that b_n does not appear in this sequence. I did find a counter-example, namely 158. This was the first counter-example thus far such that, $$158^2\mid\mid 67 = 24964\mid\mid 67 = 2496467 = 17\times 19\times 59\times 131.\tag{4 divisors}$$ Conjecture 2. I also made another conjecture that for $n\geqslant 3$, if $a_n^{\ \ 2}\mid\mid 67$ is prime, and $(a_n + 1)^2\mid\mid 67$ is also prime, then not only will $(a_n + 2)^2\mid\mid 67$ not be prime, but it will be semi-prime, which is a prime composed of strictly two prime numbers. However, I also found another counter-example, namely 144. This was also the first counter-example to this conjecture, such that $144^2\mid\mid 67$ is prime, $(144^2 + 1)\mid\mid 67$ is also prime, but $$(144^2 + 2)\mid\mid 67 = 19\times 151\times 743.\tag{3 divisors}$$ This number is not semi-prime because it is composed of three prime numbers. I extended my first conjecture for which every number $b_n^{\ \ 2}\mid\mid 67$ that is not prime will have at most 4 prime divisors. But my question is, do there exist other counter-examples to the second conjecture? Particularly counter-examples that are square numbers, like 144? And is there a counter-example to my extended first conjecture? Thank you in advance. Edit: Conjecture 2 has been proven to be false, and lots of the counter-examples of conj$_2$ are square numbers. Here are the first few among the list: $$\begin{align} 1 = 1^2 &\quad 2916 = 54^2 &\quad 5776 = 76^2 &\quad \\ 837225 = 915^2 &\quad 3111696 = 1764^2 &\quad 10259209 = 3203^2\end{align}$$

On the conjecture that if $\,\forall\{x, y, z\}\subset \Bbb{Z^+}$ squarefree, and $\ x^3 + y^3 = z^2$, then $\gcd(3, x, y) = 1$.

I made a conjecture that if $\,\forall\{x, y, z\}\subset\mathbb{Z}^+$ with x, y, z squarefree (not raised to a power greater than 1; not a perfect power), and $$x^3 + y^3 = z^2,$$ then $\gcd(3, x, y) = 1$. I was able to prove my conjecture for all z prime. Proof: Let z be a prime number. Since $(x+y)^3 = x^3 + y^3 + 3xy(x+y),$ then $$\begin{align} x^3 + y^3 &= (x+y)^3 - 3xy(x+y) \\ &= (x+y)\big((x+y)^2-3xy\big) \\ &=(x+y)(x^2 + y^2 - xy).\tag1\end{align}$$ Therefore, we need integer solutions such that $(*)\,\, x + y = x^2 + y^2 - xy$ because $(1) = z^2$, follows that $$\begin{align} 0 &= x^2 + y^2 - xy - x - y \\ &= x(x - 1) + y(y - 1) - xy \\ \Leftrightarrow 3xy &= x(x-1) + y(y-1) + 2xy.\end{align}$$ Since $3xy$ is not a square number, this means that $x \neq 3y$, $y\neq 3x$ and $3\neq xy$. Therefore $\gcd(3, x, y) = 1$ for this case, but there is also another case where $(**)\,\, x + y = z$ and $x^2 + y^2 - xy = 1$. Of course $x + y\neq 1$ because $x, y\in\mathbb{Z}^+$, thus we need to consider statement $(**)$. $$\begin{align} x^3 + y^3 &= (x+y)^2 \\ \Leftrightarrow (x+y)(x^2 + y^2 - xy) &= (x+y)^2 \\ \Leftrightarrow x^2 + y^2 - xy &= x + y\tag*{$\unicode{x21af}$ (Contradiction)}\end{align}$$ Therefore, statement $(*)$ must always be true, i.e. $\gcd(3, x, y) = 1$.$\quad\quad\quad\quad\qquad\qquad\qquad\quad\Box$ Of course if z is not prime, then $x+y$ does not necessarily have to equal $x^2 + y^2 - xy$. Take $z = 6$ for example, then $z^2 = 6^2 =6\times 6$ but it also equals 9×4, etc. Could somebody prove/disprove my conjecture for all $z\in\mathbb{Z^+}$? Along with that, is my proof valid? Thank you in advance. Edit: The symbol $\unicode{x21af}$ (Harry Potter's Scar) is used to symbolise a contradiction in this case. Most people prefer $\Rightarrow\Leftarrow$, so if you prefer that instead, treat the Scar as if it were the arrows.

A trivial prime conjecture?

For all polynomials $q\in\mathbb Z[X]$ and all $n\in \mathbb N$ $$\exists k\in\mathbb N: q(p_n)\equiv q(-2k)\pmod{p_{n+1}}$$ Where p_n is the n-th prime. This conjecture is tested for random polynomials and seems to hold. Are there counterexamples? Is it a known conjecture? Is it trivial?

Compositeness tests for specific classes of generalized repunit numbers

Can you provide proofs or counterexamples for the following two claims: First claim Let $P_m(x)=2^{-m}\cdot \left(\left(x-\sqrt{x^2-4}\right)^{m}+\left(x+\sqrt{x^2-4}\right)^{m}\right)$. Let $N_p(b)=\frac{b^p+1}{b+1}$, where p is an odd prime and b is an odd natural number greater than one . CASE(1). $b \equiv 1,9 \pmod{12}$, or $b \equiv 3,7 \pmod{12}$ and $p \equiv 1 \pmod 4$, or $b\equiv 5 \pmod{12}$ and $p \equiv 1,7 \pmod{12}$, or $b \equiv 11 \pmod{12}$ and $p \equiv 1,11 \pmod{12}$. CASE(2). $b \equiv 3,7 \pmod{12}$ and $p \equiv 3 \pmod 4$, or $ b\equiv 5 \pmod{12}$ and $p \equiv 5,11 \pmod{12}$, or $b \equiv 11 \pmod{12}$ and $p \equiv 5,7 \pmod{12}$. Let $S_i=P_b(S_{i-1})$ with $S_0=P_b(4)$. Suppose $N_p(b)$ is prime , then : $\bullet$ $S_{p-1} \equiv P_{b}(4) \pmod {N_p(b)}$ if Case(1) holds ; $\bullet$ $S_{p-1} \equiv P_{b+2}(4) \pmod {N_p(b)}$ if Case(2) holds ; You can run this test here . Second claim Let $P_m(x)=2^{-m}\cdot \left(\left(x-\sqrt{x^2-4}\right)^{m}+\left(x+\sqrt{x^2-4}\right)^{m}\right)$. Let $M_p(a)=\frac{a^p-1}{a-1}$, where p is an odd prime and a is an odd natural number greater than one . CASE(1). $a \equiv 3,11 \pmod{12}$, or $a \equiv 5,9 \pmod{12}$ and

$p \equiv 1 \pmod 4$, or $a\equiv 7 \pmod{12}$ and $p \equiv 1,7 \pmod{12}$, or $a \equiv 1 \pmod{12}$ and $p \equiv 1,11 \pmod{12}$. CASE(2). $a \equiv 5,9 \pmod{12}$ and $p \equiv 3 \pmod 4$, or $ a\equiv 7 \pmod{12}$ and $p \equiv 5,11 \pmod{12}$, or $a \equiv 1 \pmod{12}$ and $p \equiv 5,7 \pmod{12}$. Let $S_i=P_a(S_{i-1})$ with $S_0=P_a(4)$. Suppose $M_p(a)$ is prime , then : $\bullet$ $S_{p-1} \equiv P_{a}(4) \pmod {M_p(a)}$ if Case(1) holds ; $\bullet$ $S_{p-1} \equiv P_{a-2}(4) \pmod {M_p(a)}$ if Case(2) holds ; You can run this test here . I have tested these claims for many random values from this list . EDIT A command line program that implements these two tests can be found here .

Show $\lim_{n\to \infty}{|A_{n}|+|A_{n-2}| \above 1.5pt |A_{n-1}|}=2$

Question: Let $A(n)$ be a finite square $n \times n$ matrix with entries $a_{ij}=1$ if $i+j$ is a prime; otherwise equals to 0. I write $|A(n)|$ to count the number of 1's in $A(n)$. Is it true, possibly trivially, and how can we show that $$\lim_{n\to \infty}{|A_{n}|+|A_{n-2}| \above 1.5pt |A_{n-1}|}=2$$ The sequence of $A(n)$'s can be found here in Sloan. The graph below illustrates the limit. I believe I have shown the question is true, conditionally using a parity argument along with Bertrand's Postulate. Solution: It is easy to verify that $A(n)$ has exactly $2n-1$ skew diagonal. Two small lemmas. $\underline{\text{lemma 1}}:$ Observe $a_{ii}=1$ if and only if $i=1$. Consequently a_{11} is the only entry on the main diagonal of $A(n)$ equal to 1. Note $A(n)$ is symmetric since addition is commutative. So the count of 1's below the main diagonal equals the counts of 1's above the main diagonal and the two counts combined form an even number. If we remember to add the sole 1 for the entry a_{11} then there are an odd number of entries in $A(n)$. In particular $|A(n)|$ is always odd. $\underline{\text{lemma 2}}:$ As mentioned earlier every matrix $A(n)$ has $2n-1$ skew diagonals. Let S_n be the n-th skew diagonal of $A(n)$. A skew analogue of Bertrand's Postulate shows that at least one of the skews between S_n and S_{2n-2} has all of its entries equal to 1. Consequently for $n>2$ we have that there is always a skew diagonal with entries equal to 1 below the main skew diagonal. In particular $\{A(n)\}_{n=1}^\infty$ is a monotonically increasing sequence of odd integers. Lemma's 1 and 2 control the growth of $A(n)$ as $n \to \infty.$ By parity check alone as $A(n)$ grows to $A(n+1)$ the count of new 1's must be an nonzero even number. Because of this we have that $|A_n|=|A_{n-1}|+2j$ for some $j\in\mathbb{N}$, $j\neq0$. So we have the following from direct substitution \begin{align} {|A_{n}|+|A_{n-2}| \above 1.5pt|A_{n-1}|}&={\left(|A_{n-1}|+2j\right)+\left(|A_{n-1}|-2k\right)\above 1.5pt |A_{n-1}|}\\ &=2\cdot{|A_{n-1}|+j-k\above 1.5pt |A_{n-1}|}\\ &=2\cdot\left(1+{j-k\above 1.5pt |A_{n-1}|}\right)\\ \end{align} Taking limits we have \begin{align} \lim_{n\to \infty}2\cdot\left(1+{j-k\above 1.5pt |A_{n-1}|}\right)&=2+\lim_{n\to \infty}\left({j-k\above 1.5pt |A_{n-1}|}\right)\\ &=2+0\\ &=2 \end{align} This completes the proof.

What is the difference between intuition and conjecture in mathematics?

I don't know any difference between intuition and conjecture. In my opinion: A conjecture is a mathematical statement that has not yet been rigorously proved. Conjectures arise when one notices a pattern that holds true for many cases. Conjectures must be proved for the mathematical observation to be fully accepted. When a conjecture is rigorously proved, it becomes a theorem, and intuition is prediction of any thing and how it will be in the future. Question: What is the difference between intuition and conjecture in mathematics ?

About a very interesting constant g.

I was playing around with numbers like I always do, and I came up with a conjecture: $$\ln(e^{\pi + n} - e^{\pi + n - 1} - \ldots - e^{\pi + 1} - e^{\pi}) - \frac{\pi}{\sqrt{2}} \approx n$$ such that $n\in\mathbb{N}$. I then realised that the larger the value of n, the more accurate the LHS was getting closer to the RHS... ...and then it stopped. Strangely enough, it appeared that $$\ln\left(e^{\pi + n} - \sum_{i = 0}^{n-1}e^{\pi + i}\right) - \frac{\pi}{\sqrt{2}} \sim n + k$$ such that, as far as I have tested, $k \approx 0.0479330616936374724102$ for all $n\leqslant 61$. Subtracting this constant k from both sides, I see that $$\frac{\pi}{\sqrt{2}} + k \approx 2.26937453077282059591 8141.$$ Now by letting $g = \dfrac{\pi}{\sqrt{2}} + k$, is there some algebraic formula (like an infinite series) to find k? If there is, and we find it, we can find the value of g, and we would be able to write down that, $$\ln\left(e^{\pi + n} - \sum_{i=0}^{n-1}e^{\pi + i}\right) - g\sim n$$ with whatever g is equal to (algebraically speaking). For now, g is just a special constant. Thanks in advance.

A sum of sum involving binomial coefficent.(my conjecture)

While using MATLAB I found out that $\displaystyle\sum_{k=0}^{n}\frac{(\sum_{r=\max (0,k+m-n)}^{\min (k,m)}(-1)^{r}\binom{n-m}{k-r}\binom{m}{r})^{2}}{\binom{n}{k}} =\frac{2^{n}}{\binom{n}{m}} $ hold for all $m\leq n\leq 100\ $ and I proved that the equality hold for all $m=0,1,n-1,n\ $ but I couldn't prove it in general (or disprove). Any help is appreciated! Thanks in advance.

Equiangular lines in $\mathbb{C}^d$.

Zauners' conjecture regarding equiangular lines for any $\mathbb{C}^{d}$, holds for many dimesnions, like 17 or more(43, 31, and so on). This conjecture gives the number of equiangular lines in a given complex space $\mathbb{C}^d$. A similar result shows that for Euclidean spaces, given an angle, the number of equiangular lines can be found, result here this result is for the case of a given angle, finding the number of equiangular lines like in Zauners' conjecture (over $\mathbb{C}^{d}$), but for a given angle. Is there a number(it could be a lower/upper bound, or like Zauners' conjecture - exact), but with the constraint that it is for a given angle over $\mathbb{C}^{d}$?

If $\frac{σ(x)}{x}=\frac{p+2}p$ where p is an odd prime, does it follow that x is an odd square?

(This question is related to the latest comment underneath this MSE question.) Let $$\sigma(x)=\sum_{d \mid x}{d}$$ be the sum of the divisors of x. Denote the abundancy index of x by $$I(x)=\frac{\sigma(x)}{x}.$$ Here is my question: If $I(x)=\dfrac{p+2}{p}$, where p is an odd prime, does it follow that x is an odd square? From the equation $$p\sigma(x)=(p+2)x$$ I can only prove that x is an odd square when x is odd. But what about if x is even? That is, if $I(x) = \dfrac{p+2}{p}$, where p is an odd prime, must it necessarily be the case that x is odd?

Conjecture over this series, and its generalisation

PART I The following series, according to W. Mathematica, does converge to $$\sum_{k = 1}^{+\infty} \frac{e^{-k}}{k^k \sqrt{k}} = 0.3929049383779132(...)$$ The previous result can be written in terms of elementary numbers plus the Euler constant, as follows: $$0.3929049383779132 \approx \frac{-92-95 e+86 e^2}{2 \left(130-4 e+33 e^2\right)}$$ Question Is that conjecture true? Probably it's a lack of mine but I cannot manage to make W. Mathematica to spit out more digits of the previous number. PART II The previous series was actually a special case for $x = 1$ of the more general series: $$\sum_{k = 1}^{+\infty} \frac{x^k e^{-k}}{k^k \sqrt{kx}}$$ Question: Is there a close form for this? I tried with many values of x and the series always gets a numerical result, but Mathematical cannot give me a close form. I am not assuming a priori it does exist, but many times people found out close forms whereas software could not.

If $q^k n^2$ is an odd perfect number with Euler prime q, does this equation imply that $k=1$?

Let $\sigma(x)$ be the sum of the divisors of x. Denote the deficiency of x by $D(x) := 2x - \sigma(x)$, and the sum of the aliquot divisors of x by $s(x) := \sigma(x) - x$. Here is my question: If $q^k n^2$ is an odd perfect number with Euler prime q, does this equation imply that $k=1$? $$D(q^k)D(n^2)=2s(q^k)s(n^2)$$ I only know that $k=1$ is true if and only if (one of) the following conditions hold: (1) $\sigma(n^2)/q \mid n^2$ (2) $D(n^2) \mid n^2$ (3) $\gcd(n^2, \sigma(n^2)) = D(n^2)$ Source of Equation From the fundamental equation $$\frac{\sigma(n^2)}{q^k} = \frac{2n^2}{\sigma(q^k)} = \gcd(n^2, \sigma(n^2))$$ we obtain $$\frac{2n^2 - \sigma(n^2)}{\sigma(q^k) - q^k} = \frac{D(n^2)}{s(q^k)} = \gcd(n^2, \sigma(n^2))$$ and $$\frac{\sigma(n^2) - n^2}{\frac{2q^k - \sigma(q^k)}{2}} = \frac{2s(n^2)}{D(q^k)} = \gcd(n^2, \sigma(n^2)),$$ using the identity $$\frac{A}{B}=\frac{C}{D}=\frac{C-A}{D-B}.$$ Reference Conditions Equivalent to the Descartes-Frenicle-Sorli Conjecture on Odd Perfect Numbers

A Simple Calculus view on Fermat's Last Theorem

My question (more of a hypothesis really) is basically this: If a function $f(x)$ is defined such that $f'(x)$ is not constant and never the same for any 2 values of x. Then there do not exist positive integers a,b,c and $a\le b\le c$ such that, $$\int_0^{a} f(x)dx = \int_b^{c} f(x)dx\tag1$$ Taking $f(x)=x^n$ then for $n \gt 1$, (1) becomes Fermat's Last Theorem,

while for $n=1$, (1) becomes $a^2 + b^2 = c^2$ Maybe this has something to do with the "curviness" (I am 16 so please forgive me for non-technical language) of the graphs of x^n since for $n=1$ the graph is linear and for $n>1$ the graph is curvy. My school teachers are not talking to me about this because "it is out of syllabus", so I thought maybe this community could help.

A conjectured vanishing sum involving the Thue-Morse sequence

Let's define t_n by the recurrence $$t_0 = 1, \quad t_n = (-1)^n \, t_{\lfloor n/2\rfloor}.\tag1$$ It is easy to see that $|t_n|=1$, and the signs follow the same pattern as the Thue-Morse sequence: $$1,\,-1,\,-1,\,1,\,-1,\,1,\,1,\,-1,\,-1,\,1,\,1,\,1,\,-1,\,1,\,-1,\,-1,\,1,\,1,\,...\tag2$$ (see this question for an example of a non-recursive formula for t_n). Now, define: $$\mathcal{S}(m, n)=\sum_{k=0}^{2^n-1}t_k\,k^m, \quad \color{gray}{m,\,n\in\mathbb{Z}^+.}\tag3$$ Computing some values of this sum immediately leads to the following conjecture: $$\text{For all }\, n>m,\,\,\mathcal{S}(m, n)=0.\tag{$\diamond$}$$ (e.g. for $m=2$ and $n=3$ we have $0-1-4+9-16+25+36-49=0$). How can we prove it? Is it a known result?

A limit involving the Thue-Morse sequence

(it is a follow-up on my previous question) Let's define t_n by the recurrence $$t_0 = 1, \quad t_n = (-1)^n \, t_{\lfloor n/2\rfloor}.\tag1$$ It is easy to see that $|t_n|=1$, and the signs follow the same pattern as the Thue-Morse sequence: $$1,\,-1,\,-1,\,1,\,1,\,-1,\,1,\,1,\,1,\,-1,\,-1,\,1,\,1,\,1,\,-1,\,1,\,1,\,-1,\,-1,\,1,\,1,\,...\tag2$$ (see this question for an example of a non-recursive formula for t_n). Now, let: $$\mathcal{L}(z)=\lim_{n\to\infty}\,\sum_{k=1}^{2^n-1}t_k\,k^z.\tag3$$ I conjecture that the following propositions hold: $\color{gray}{\text{(a)}}$ The limit $\mathcal{L}(z)$ exists for all $z\in\mathbb C$. $\color{gray}{\text{(b)}}$ $\mathcal{L}(z)$ is an entire function of z. $\color{gray}{\text{(c)}}$ $\mathcal{L}(z)=0$ if and only if $z\in\mathbb Z^+$. Can we prove these conjectures? Can we find a different representation of $\mathcal{L}(z)$? Does this function have any interesting properties? Update: The "if" part of the conjecture $\color{gray}{\text{(c)}}$ is certainly true. I am now pretty sure the "only if" part fails at some points on the imaginary axis (e.g. near $z\approx i\,4.53236...$; is it exactly $i\,\pi/\ln2$?). I am still wondering if there are any zeros except positive integers and off the imaginary axis. Update: I found a very relevant and interesting paper (preprint) by Giedrius Alkauskas, Dirichlet series associated with Thue-Morse sequence$^{[1]}$$\!^{[2]}$ (be aware that the author claims$^{[3]}$ some results in it may be incorrect). Here is my attempt to plot the function for a range of real arguments:

A few conjectured limits of products involving the Thue-Morse sequence

(related to my previous questions$^{[1]}$$\!^{[2]}$) Let's define the signed Thue-Morse sequence t_n by the recurrence $$t_0 = 1, \quad t_n = (-1)^n \, t_{\lfloor n/2\rfloor},\tag1$$ or by the generating function $$\sum_{n=0}^\infty t_n \, x^n=\prod_{n=0}^\infty\left(1-x^{2^n}\right).\tag{$1^\prime$}$$ It seems that the following conjectures hold: $$\lim_{n\to\infty}\prod_{k=0}^{2^n-1}\left(k+\tfrac12\right)^{t_k}\stackrel{\color{gray}?}=\frac12\tag2$$ $$\lim_{n\to\infty}\prod_{k=0}^{2^n-1}\left(k+1\right)^{t_k}\stackrel{\color{gray}?}=\frac1{\sqrt2}\tag3$$ $$\lim_{n\to\infty}\prod_{k=0}^{2^n-1}\left(k+1\right)^{(-1)^k\,t_k}\stackrel{\color{gray}?}=\frac1{2\sqrt2}\tag4$$ How can we prove these? Are there any other limits of products similar to these?

Does there exist an odd natural number $N = xy$ satisfying $D(x)D(y) = 2s(x)s(y)$?

Preamble: I apologize in advance if what I am asking for in this question, I could get an answer easily so myself, for example by coding a short Mathematica script. It is just that I have not yet studied the rudiments of Mathematica (or even Python) scripting, so I am not there yet. This question is a follow-up to this earlier MSE question. Let $\sigma(z)$ be the sum of the divisors of $z \in \mathbb{N}$. Denote the deficiency of z by $D(z) := 2z - \sigma(z)$ and the sum of the aliquot parts of z by $s(z) := \sigma(z) - z$. Here is my question: Does there exist an odd natural number $N = xy$ satisfying $D(x)D(y) = 2s(x)s(y)$?

Is this tiny conjecture true concerning α true?

As part of a problem that i am trying to solve i would like to know if the following conjecture is true. Conjecture. Given a non-zero vector α in a finite dimensional vector space W there exist a basis for W say $w_1,w_2,...,w_m$ such that $\alpha = a_1w_1+a_2w_2+\cdot\cdot\cdot+a_mw_m$ where $a_j\neq 0$ $\forall j\in\{1,2,...,m\}$ and $m = \dim W$. The Field of Scalars is either $\mathbf{R}$ or $\mathbf{C}$.

An inequality involving three consecutive primes

Can you provide a proof or a counterexample to the following claim : Let p,q,r be three consecutive prime numbers such that $p\ge 11 $ and $p<q<r$, then $\frac{1}{p^2}< \frac{1}{q^2} + \frac{1}{r^2}$. I have tested this claim up to 10^{10} . For $p>5$ we get $\pi(2p)-\pi(p) \ge 2$, a result by Ramanujan . This means that $q<2p$ and $r<2p$, so $\frac{1}{2p}<\frac{1}{q}$ and $\frac{1}{2p}<\frac{1}{r}$ which implies $\frac{1}{p} < \frac{1}{q} + \frac{1}{r}$. If we square both sides of inequality we get $\frac{1}{p^2} < \frac{1}{q^2} + \frac{2}{qr} + \frac{1}{r^2}$. Now , I don't know how to rule out term $\frac{2}{qr}$.

"Schäffer's conjecture" on equation $1^k+2^k+\cdots+x^k=y^n$

In 1956 J. J. Schäffer proved that the equation $$1^k+2^k+\cdots+x^k=y^n$$ for fixed integers $k\ge1,n\ge2$ has only finitely many solutions in positive integers unless $(k,n)\in\{(1,2),(3,2),(3,4),(5,2)\}$ [see Theorem 2, p. 27 in the file's numbering of pages]. Furthermore, he conjectured the equation has only trivial solution $x=y=1$ except $(k,n,x,y)=(2,2,24,70)$ (and excluding those four pairs of (k,n)). I was able to find partial results, that the conjecture is true for $k\le11$ [see this] $n=2,k\le58$ [mentioned there as well] $k<170$ odd and even n [see this one] The newest paper (3.) was published in 2007 and I didn't find newer articles. So here is my question, is Schäffer's conjecture still an open problem?

A question on entropy of natural numbers

This question is more of a conjecture, but I am not posting it to mathoverflow, since I am not a professional mathematician and I do not know if it is research related: Let $n=p^{a} s$, p be the smallest prime dividing n, $v_p(n) = a$, $n\equiv 1(2)$,$\sigma(n) = 2n$. Then we must have $p>2$. Let $m=2^a s $. Then we have $$\sigma(m)= \sigma(2^a)\sigma(s)= \frac{\sigma(2^a)\sigma(n)}{\sigma(p^a)}$$. Since $2<p$ we have $H(2^a) < H(p^a)$ where H is the entropy of n defined here: Entropy of a natural number. It follows that: $$H(n) = H(p^a s) = H(p^a)+H(s) > H(2^a) + H(s) = H(m) = \log(\sigma(m))-\frac{1}{\sigma(m)}\sum_{d|m}{d \log(d)} = \log(\frac{\sigma(2^a)\sigma(n)}{\sigma(p^a)})-\frac{1}{\sigma(m)}E(m)$$, where $E(k) = \sum_{d|k} {d \log(d)}$. Since $\log(x) \ge 1 - 1/x$ we have $$ H(n) > H(m) = \log(\sigma(n))+\log(\frac{\sigma(2^a)}{\sigma(p^a)})-\frac{E(m)}{\sigma(m)}\ge\log(\sigma(n))+1-\frac{\sigma(p^a)}{\sigma(2^a)}-\frac{E(m)}{\sigma(m)}$$ which is equal to: $$\log(\sigma(n))+1-\frac{\sigma(n)}{\sigma(m)}-\frac{E(m)}{\sigma(m)}$$ If we can prove that, the last quantity is greater than or equal to $\log(\sigma(n))-\frac{E(n)}{\sigma(n)}= H(n)$, we would get the contradiction: $$H(n)>H(m) \ge H(n)$$ So we have to prove that: $$1 - \frac{\sigma(n)}{\sigma(m)}-\frac{E(m)}{\sigma(m)} \ge - \frac{E(n)}{\sigma(n)}$$ We have the following identities: $$E(m) = \sigma(2^a)E(s)+\sigma(s)E(2^a)$$ $$E(n) = \sigma(p^a)E(s)+\sigma(s)E(p^a)$$ Furthermore one can show that: $$E(p^a) = p \log(p) \frac{p^{a+1}-1-(a+1)p^a(p-1)}{(p-1)^2}$$ which can be applied to compute $E(2^a)$. So my question is if somebody can help me prove the inequality above or show an "example" where it fails, if this is not too much to ask.

Where is the mistake in the argument? (And two conjectures)

Let n be a natural number. $\Omega = \{ d : d | n \}$, For $A\subset \Omega$ define the probability for A as : $$P(A) = \frac{1}{\sigma(n)}\sum_{d\in A}{d}$$ Consider the set $B = \{d \in \Omega |d \equiv 0 (2) \}$. Let $a = v_2(n)$. Then (first conjecture) $$P(B) = \frac{2^{a+1}-2}{2^{a+1}-1}$$ We have $E(d) = \sum_{d|n} {d \cdot P(d)} = \sum_{d|n} { d \cdot \frac{d}{\sigma(n)}} = \frac{\sigma_2(n)}{\sigma(n)}$ Second conjecture: $|B| = a \cdot b$, where $n = 2^a \cdot p_1^{a_1}\cdots p_r^{a_r}$ is the factorization of n, with a possibly $=0$ and $b = (a_1+1)\dots(a_r+1)$. Consider $Z = \sum_{d \in B} {d}$ and consider the random variable: $Y_d = 1$ if $d \equiv 0 (2) $, otherwise $= 0$. Then $Z = \sum_{d|n} Y_d d$ is a random variable. Then on the one hand we have: $E(Z) = \sum_{d \in B}{E(d)} = \sum_{d \in B}{\frac{\sigma_2(n)}{\sigma(n)}} = a b \frac{\sigma_2(n)}{\sigma(n)}$ On the other hand we have $P(B) = \frac{Z}{\sigma(n)}$ hence solving for Z we get: $$Z = \sum_{d|n}{d} \cdot \frac{2^{a+1}-2}{2^{a+1}-1}$$ From this it follows that: $$E(Z) =

\frac{2^{a+1}-2}{2^{a+1}-1} \sum_{d|n}{E(d)} = \frac{2^{a+1}-2}{2^{a+1}-1} \sum_{d|n}{\frac{\sigma_2(n)}{\sigma(n)}} = \frac{2^{a+1}-2}{2^{a+1}-1} \tau(n) \cdot \frac{\sigma_2(n)}{\sigma(n)}$$ Hence we get: $$a b \frac{\sigma_2(n)}{\sigma(n)} = \frac{2^{a+1}-2}{2^{a+1}-1} \tau(n) \cdot \frac{\sigma_2(n)}{\sigma(n)}$$ from which it follows: $$ab = \tau(n) \cdot \frac{2^{a+1}-2}{2^{a+1}-1}$$ But for example for $n=6$ this is wrong, so where is the mistake in the argument? If you happen to have a proof for one of the conjectures, that would also be fine.

A conjecture on bounded complex partial sums

A friend of mine has made the following conjecture, but we don't know how to prove it. Let $(a_n)_{n\in \mathbb {N}}$ be a strictly increasing sequence of natural numbers. Suppose that for every complex $z\neq 1 $ with $|z|=1$, there exists a constant $C_z>0 $ verifying $$\forall N\geq 0, \qquad \left|\sum_{i=0}^N z^{a_i}\right| <C_z$$ Then the sequence $(a_n) $ contains all but finitely many natural numbers. For exemple, if $a_n=2n$, the property is not verified with $z=-1$. Can you find a proof or a counterexample?

Can the following argument be pushed to a full proof that $(p + 2)/p$ is an outlaw if p is an odd prime?

This is related to this earlier MSE question. Let $\sigma(x)$ be the sum of the divisors of x, and denote the abundancy index of x by $I(x):=\sigma(x)/x$. If the equation $I(a) = b/c$ has no solution $a \in \mathbb{N}$, then the rational number b/c is said to be an abundancy outlaw. In what follows, let p be an odd prime. In the earlier question, it is shown that: (a) If $I(n) = (p+2)/p$, then n is an odd square. (b) If $I(n) = (p+2)/p$, then $p \mid n$. So now suppose to the contrary that $I(n) = (p+2)/p$. From (a) and (b), since p is a prime number, then $p^2 \mid n$. It follows that $$\frac{p^2 + p + 1}{p^2} = I(p^2) \leq I(n) = \frac{p+2}{p},$$ whence there is still no contradiction. From the divisibility constraint $p^2 \mid n$, we have that $p^2 \leq n$. We claim that $p^2 \neq n$. Suppose to the contrary that $p^2 = n$. Then we have $$\frac{\sigma(n)}{n} = \frac{p+2}{p} = \frac{p(p+2)}{p^2}$$ so that $$p^2 + p + 1 = \sigma(p^2) = \sigma(n) = p^2 + 2p,$$ which contradicts the fact that p is an odd prime. This implies that $p < \sqrt{n}$, which further means that $$\gcd(n, \sigma(n)) = \frac{n}{p} > \sqrt{n} > {10}^8$$ where the lower bound $n > {10}^{16}$ is due to Richard F. Ryan, "Results concerning uniqueness for $\sigma(x)/x = \sigma(p^n q^m)/(p^n q^m)$ and related topics, International Math. J., 2002 , V2#5pp497-514". Here is my question: Can the preceding argument be pushed to a full proof that $(p + 2)/p$ is an outlaw if p is an odd prime?

On a conjecture that if $2\left(p_n+p_{n-1}\right)\equiv -1\pmod {n^2}$ then $n=11$ only.

Conjecture: We denote by p_n the n^{th} prime number. If $2\left(p_n+p_{n-1}\right)\equiv -1\pmod {n^2}$, then $n=11$ only. How must one be able to prove / disprove this supposed claim? I had come up with this conjecture, but am a little stuck in trying to prove it. Attempt: I know that the congruence can be similarly written as, $2\left(p_n+p_{n-1}\right) = mn^2 - 1$ for some $m\in\mathbb{Z}$, the set of all integers. However, I will consider the case where $m=1$, or where $2\left(p_n+p_{n-1}\right)$ $ = (n+1)(n-1)$. Of course now, we find that n must be odd and greater than 1. Replace n with n_k, namely, the k^th odd number. Then, $$\frac{n_k+1}{2} = k \ \land \ \frac{n_k-1}{2} = k-1.\tag{$\land$ is read as and}$$ Therefore, $p_{n_k}+p_{n_k-1} = k(n_k-1) = (k-1)(n_k+1)$. This means that $\left\{k,k-1\right\}\mid p_{n_k} + p_{n_k-1}$. So, $p_{n_k}+p_{n_k-1}$ has to be squarefree, leaving out primes 3 and 5 since $5+3=8=2^3$ and also 17 and 19 since $19+17=36=6^2$. I do not know where to go from here. Am I taking the correct approach? Is there anything important I should know abut prime numbers (e.g. any lemmas and such) that will be useful in (dis)proving my conjecture? Hints are mostly appreciated, but you can provide a full and disclosed answer if you wish. Thank you in advance.

Is 387420547 another counter example to John H. Conway's Problem 5?

John H. Conway is a mathematician who created these five $\$1000$ problems. They are just problems that he discovered himself and that relate to mathematics, mainly on a recreational level. Anyone to have "solved" one of the problems (by "solved", I mean provide a proof or counterexample, etc) will win $\$1000$, and will win that for every problem solved. I looked at Problem 5 in particular, and someone had found a counterexample to the proposition and won the prize. You can go here to check out the problems, and Problem 5 is the very last one. It mentions that 20 seems to (also) be a counterexample, but it has not been proven to be. However, I believe I might have found myself another potential counterexample, namely, $$387420547.$$ This number cannot be generated from any other

numbers, as what can happen in Problem 5. This is because in the problem, you can join primes together to make a new number that might be prime. In the number above, there are n prime numbers such that when you concatenate them, they make this number. After going to the link and reading the problem, you will understand why this is very important. If you cannot access the link, please let me know, and I will write out the problem in this post for all to see. My question is, Is the number above an actual counterexample? It seems like it never climbs to a prime, no matter how many iterations I make. Can it be checked for certain? Thank you in advance.

Confirmation of Proof: $\pi_n + p_a + p_b \geqslant \sum_{i=1}^4 x_i$.

I was messing around with numbers and I made the following conjecture: Conjecture: Let π_n be the n^{th} perfect number; p_a be the prime after π_n and p_b be the prime before π_n. Then, one may always see that$$\begin{align}\pi_n^{ \ \ 2}+p_a^{ \ \ 2}+p_b^{ \ \ 2}&=\sum_{i=1}^4x_i^{ \ 2}\tag{$\exists x_i\in\mathbb{Z}^+$} \\ \Leftrightarrow \pi_n + p_a + p_b&\geqslant\sum_{i=1}^4x_i\tag{with equality $\Leftrightarrow n = 1$}\end{align}$$ (Developed this conjecture from here.) Does anybody know how to prove /disprove this? I know that by Lagrange's Four-Square Theorem, the first equality is true. However, I am not particularly good at inequalities, strict and nonstrict. I know that every perfect number is of the form $2^{q-1}\left(2^q-1\right)$ for a prime q and for all primes 2^q-1, thus far. (It is not proven whether or not there exists an odd perfect number, which would mean that 2^{q-1} does not divide that, supposing it exists). Thus, $\pi_n^{ \ \ 2} = 4^{q-1}(4^q - 2^{q+1}+1)$ but this does not really help me. So, I made a new substitution: $$\pi_n = (2^q-1)^2 - \sum_{i=1}^{2^{q-1}-1}(4k-1).\tag{provable by induction}$$ This looks much more appropriate to work with. Squaring this and simplifying, $$\begin{align}\pi_n^{ \ \ 2} &= \left((2^q-1)^2-\frac 13(3\cdot 2^q-4^q-2)\right)^2 \\ &=\cdots \tag{lots of working out}\\ &= 4^{q-1}(2^q-1)^2.\end{align}$$ But this is exactly what we had before (also proving that it is a perfect number). What do I do in order to (dis)prove my conjecture? Thank you in advance.

Do odd numbers n satisfying $\gcd(n, \sigma(n)) > \sqrt{n}$ have a special form?

Let $\sigma(n)$ denote the sum of divisors of the positive integer n. Using Sage Cell Server, I was able to get the following odd numbers $n < 5000$ satisfying $\gcd(n, \sigma(n)) > \sqrt{n}$: $$117 = {{3}^2}\cdot{13}$$ $$135 = {{3}^3}\cdot{5}$$ $$585 = {{3}^2}\cdot{5}\cdot{13}$$ $$775 = {{5}^2}\cdot{31}$$ $$819 = {{3}^2}\cdot{7}\cdot{13}$$ $$891 = {{3}^4}\cdot{11}$$ $$1287 = {{3}^2}\cdot{11}\cdot{13}$$ $$1305 = {{3}^2}\cdot{5}\cdot{29}$$ $$1485 = {{3}^3}\cdot{5}\cdot{11}$$ $$1989 = {{3}^2}\cdot{13}\cdot{17}$$ $$2295 = {{3}^3}\cdot{5}\cdot{17}$$ $$2793 = {3}\cdot{{7}^2}\cdot{19}$$ $$3515 = {5}\cdot{19}\cdot{37}$$ $$4095 = {{3}^2}\cdot{5}\cdot{7}\cdot{13}$$ $$4455 = {{3}^4}\cdot{5}\cdot{11}$$ $$4655 = {5}\cdot{{7}^2}\cdot{19}$$ Is this surprising? Or is there an underlying explanation for this phenomenon? Updated Question (Added October 30, 2018) Under what suitable conditions does it follow that $3 \mid n$, if n is an odd number satisfying $\gcd(n,\sigma(n)) > \sqrt{n}$? Note that it follows from the inequality $\gcd(n,\sigma(n)) > \sqrt{n}$ that n must be composite.

Is this integral $\int_0^\infty\frac{\cos(a x+ 2b \arctan x)}{x^2+1}dx$ exactly zero when $b\in\mathbb{N}$?

I recently encountered this integral $$\int_0^\infty\frac{\cos(a x+ 2b \arctan x)}{x^2+1}dx$$ which suspiciously close to 0 for nonzero integer values of b, as indicated by numerical calculations. When b is not an integer it is not 0. Based on my experiments I conjecture that $$\int_0^\infty\frac{\cos(a x+ 2b \arctan x)}{x^2+1}dx=0,~~~~b\in \mathbb{Z}\setminus \{0\}.$$ Question. Is the above conjecture true?

Is my proof correct on how k must be a power of 2? Are there other proofs?

So I was looking at the Fermat Primes. These are primes of the form 2^k+1 for a natural number k, such that I define by $\mathbb{N}:=\big\{1,2,3,\ldots\big\}$ and $0\notin \mathbb{N}$. We denote by F_1 the first Fermat Prime; F_2 the second Fermat Prime; et cetera up to F_k. Thus far, however, only 5 Fermat Primes are known. They are the following, respectively: $$3,5,17,257,65537,\ldots$$ I write $(\ldots)$ because I assume that there exist more Fermat Primes, but it is a conjecture that the above Fermat primes are the only ones. I introduce this to you in the event that you do not know of them, because my question very much relates to these Fermat Primes. If 2^k+1 is prime, then must it be true that k is strictly a power of 2? I noticed that, $$\begin{align}3&=2^{2^0}+1\\ 5&=2^{2^1}+1 \\ 17&=2^{2^2}+1 \\ 257&=2^{2^3}+1 \\

65537&=2^{2^4}+1.\end{align}$$ Attempt at Proof: I proved that k is even, because supposing otherwise implies that $k=2j+1\,\exists j\in\mathbb{N}$ and $$2^k+1=2^{2j+1}+1=2^{2j+1}-(-1)^{2j+1}\stackrel{\centerdot}{:}2-(-1)=3.\tag*{$\bigg(\begin{align}&\text{$a\stackrel{\centerdot}{:}b$ is read as a} \\ &\text{is divisible by b.}\end{align}\bigg)$}$$ Ergo, 2^k+1 is not prime if k is odd; k must be even. $\;\bigcirc$ Now if k is even, then $k=2j$ and $$2^k+1=2^{2j}+1=4^j+1.$$ If j is odd, then likewise, as similarly demonstrated before, $$4^j+1=4^j-(-1)^j\stackrel{\centerdot}{:}4-(-1)=5.$$ Ergo, $l\nmid k\,\exists l$ odd; k must be a power of 2 as it will only then have no odd divisors. $\;\bigcirc$ Is my proof correct? I don't see anything wrong with it, but if it is correct, are there other (better) proofs? Also, is there anything new on Fermat Primes; particularly, are there any other general constraints on k? How far has the conjecture been tested for? I checked the first 250 Fermat Primes and it seems like the conjecture is true. (If you want, you can go here, type x=2;x=2x-1;c<=250;x and then wait a minute before the first 250 Fermat Primes appear. I still have to thank one of the users on the MSE who introduced me to the site accessible via the link.) Thank you in advance.

Does the prime sequence satisfy $p_n+p_m \le p_{n+m} < p_n p_m$?

I did some experiments in SAGE and it seems like the prime sequence p_n satisfies: $$p_n+p_m \le p_{n+m} < p_n p_m$$ for $(n,m) \neq (1,1)$. For $n=1$ the last inequality is Bertrand's postulate. Here is some SAGE code to test this for some primes: lp = list(primes(10000)) for n in range(len(lp)): for m in range(len(lp)): pn = lp[n] pm = lp[m] pnm = nth_prime(n+m+2) print pn*pm>=pnm,pnm>=pn+pm, n+1,m+1,n+m+2,pn,pm,pn*pm,pnm Is this something known (if it is true)? And if so, how does one prove or disprove it, are there heuristics?

Conjectured inequality: $\frac{p_{2n+1}-1}{2}\geqslant p_{n+1}+2(n+1)^{2/(n-1)}+\frac12\log_{4}^2(n-6)\qquad(n>6)$

I was inspired by this post to look at some prime numbers and see if I can find a bound. In the post, a conjecture was made with variables m and n such that $(m,n)\neq (1,1)$ respectively. I was able to prove that if it was true, then $m=n$ would imply a tighter upper bound for p_{n+1}. A current upper bound for p_{n+1} is $2p_n$, but the OP's conjecture would imply that $2p_{n+1}<p_{2n+1}$ which is tighter and better than the inequality, $p_{n+1}<2p_n$. Doing some tests, I thought that a better inequality would be that $2p_{n+1}\le p_{2n+1}-1$, but then I decided to do some more tests and I came up with a conjecture. Conjecture: $$\begin{align}\frac{p_{2n+1}-1}{2}&\geqslant p_{n+1}+2(n+1)^{2/(n-1)}\underbrace{+\,\frac 12\log_4^2(n-6)}_{\text{recent edit}}\tag{$n>6$} \\ \text{with equal}&\text{ity iff $n=7$.}\end{align}$$ Can this be proven/disproven? Thank you in advance. Edit: For a tighter bound, I added the term ${}^1/{}_2\log_{4}^{2}(n-6)^\dagger$ to the RHS (Right-Hand Side). †By $\log_b^2(x)$, I mean $\big(\log_b(x)\big)^2$.

Conways 99 graph problem

The Conway 99 graph problem is stated here as one of 5 problems. My question is this: Is there somewhere a list of examples with "Conway graphs" with fewer then 99 vertices? Or can you provide examples with fewer than 99 vertices? Definition of "Conway graph": It is a simple undirected graph $G=(V,E)$ with the following property: (1) $\forall (x,y) \in E: \exists ! z \in V: (x,z),(y,z) \in E$ (2) $\forall (x,y) \in E^c: \exists ! (z,w) \in V \times V: (x,z),(x,w),(y,z),(y,w) \in E$ (The definition is from here: https://arxiv.org/pdf/1707.08047.pdf) The Conway 99 graph problem asks if there exists a "Conway graph" with 99 vertices. I am searching for examples of "small" Conway graphs. Edit: Given the answer below, the next non trivial graph with 9 vertices is: $G(2,1)$ http://mathworld.wolfram.com/GeneralizedQuadrangle.html or the same graph: $T(3,3)$: http://mathworld.wolfram.com/TorusGridGraph.html This paper of Berlekamp might also be of interest where the graph with 243 vertices is constructed.

On a conjecture that $P_n^{\,2}+5^2+2^k=(P_n-1)^2+l^2$.

I was looking at perfect numbers and came across something that might serve a little interesting. Denote by P_n the n^th perfect number, then there appears to always exist $k\in\mathbb{W}$ and $l\in\mathbb{Z}$ such that $$P_n^{\,2}+5^2+2^k=(P_n-1)^2+l^2.\tag{$\verb|Conjecture|$}$$ for which $\mathbb{W}:= \mathbb{N}\cup\big\{0\big\}=\big\{0,1,2,3,\ldots\bigr\}$; id est, the whole numbers. Here is what I have discovered thus far, given that $(6,28,496)=(P_1,P_2,P_3)$ respectively: $$\begin{align}6^2+5^2+2^6&=5^2+10^2 \\ 28^2+5^2+2^0&=27^2+9^2 \tag*{$\begin{pmatrix}(k,l)\,\,=&(6,10)&\text{resp.}\\ (k,l)\,\,=&(0,9)&\text{resp.} \\ (k,l)\,\,=&(3,32)&\text{resp.}\end{pmatrix}$}\\ 496^2+5^2+2^3&=495^2+32^2.\end{align}$$ This is as far as I have tested. I know that for every perfect number P_n, there exists a prime number p such that $P_n=2^{p-1}(2^p-1)$ thus far (or at least, for every even perfect number), but this does not help me prove the conjecture. It is also conjectured that every perfect number is the sum of three cubes, but supposing this is valid does not help me prove this conjecture either. And, writing the equation like the following does not help as well. $$2^k+(P_n+l)(P_n-l)=(P_n+4)(P_n+6).$$ Can it be verified whether or not my conjecture holds water? Thank you in advance.

Approaches to Brocard's problem

The brocard problem is an unsolved problem that asks how many integers m and n exist such that $n! + 1 = m²$ More specifically it conjectures there are only three such numbers. What are some interesting ways to approach this conjecture? I've being playing around with it for over an hour and I tried the following approach. For any n, what is the smallest integer a, such that $n! + a = m²$? I created a function $v(n!)=a$ and now restated the conjecture in the following terms. $ v(n!) > 0 $ for all n except 4,5,7 I checked to see if v(n!) had any interesting pattern and as expected I found none. The next natural thing I wanted to do was to graph the function. To do this I need to somehow make n!, naturally we can do this with the gamma function. $v(\gamma(n))$. I am no expert on the gamma function, but I'd be really interested to see what patterns could emerge from such extensions. Do you know any papers/books discussing interesting approaches to resolving this conjecture?

On a conjecture that $\sum\limits_{n=1}^k\frac{1}{\pi^{1/n}p_n}\stackrel{k\to\infty}{\longrightarrow} 2$.

I have made the following conjecture, and I do not know if this is true. Conjecture: \begin{equation*}\sum_{n=1}^k\frac{1}{\pi^{1/n}p_n}\stackrel{k\to\infty}{\longrightarrow}2\verb| such that we denote by | p_n\verb| the | n^\text{th} \verb| prime.|\end{equation*} Is my conjecture true? It seems like it, according to a plot made by Wolfram|Alpha, but if it does, then it converges.... very.... very, slowly. In fact, let $k=5000$, then the sum is approximately equal to 1.97, which just proves how slow it would be. Is there a way of showing whether or not this is indeed convergent? For any other higher values of k, it seems that it is just too much for Wolfram|Alpha to calculate, and it does not give me a result when I let $k=\infty$. Also, for users who might not understand the notation, we can similarly write that $$\sum_{n=1}^\infty\frac{1}{\pi^{1/n}p_n}=2\qquad\text{ or }\qquad\lim_{k\to\infty}\sum_{n=1}^k\frac{1}{\pi^{1/n}p_n}=2.$$ Also, without Wolfram|Alpha, I have no idea how to approach this problem in terms of proving it or disproving it. Does the sum even converge at all? If so, to what value? Any help would be much appreciated. Thank you in advance. Edit: I looked at this post to see if I could rewrite my conjecture as something else in order to help myself out. Consequently, I wrote that $$\sum_{n=1}^k\frac{1}{\pi^{1/n}p_n}\stackrel{k\to\infty}{\longleftrightarrow}4\sum_{n=1}^\infty\frac{1}{n^k+1}\tag{$\text{LHS}=2$}$$ since both sums look very similar. Could this be of use?

A conjecture regarding a strange infinite sum

Numerical calculations indicate that the following conjecture is true $$ \sum _{n=0}^{\infty} \frac{\prod _{k=0}^{n-1} \left(x+e^{-k}\right)}{\prod _{k=0}^n \left(1+te^{-k}\right)}t^n =\frac{1}{1-xt}.\tag{1} $$ Here the $n=0th$ term of the sum is $\frac{1}{1+t}$ to avoid confucion. Question. Is the conjecture (1) correct? This sum emerged in certain birth and death process calculations. I have no idea how to prove it.

A conjectured formula for the polylogarithm of a negative integer order

I discovered the following formula while working on the sequence A141697 from the OEIS. I have no idea whether it is something trivial or not. I would be very happy to know more about it. $$ \textrm{Li}_\nu\left(z\right)= \frac { 6 (1+z)^{-\nu-1} + \displaystyle\sum_{k=0}^{-\nu-1} \displaystyle\left(-6 \displaystyle{{-\nu-1}\displaystyle\choose k}+7\sum_{j=0}^{k+1}(-1)^j (k-j+1)^{-\nu} {{-\nu+1}\ \choose j} \right) z^k } { 7 (1 - z)^{-\nu+1} }z $$ when ν is a negative integer. In case I mistyped the formula, here are my codes in two different languages: For Pari-GP: mypolylog(n, x) = { (6*(x+1)^(-n-1) + sum(k=0,-n-1, (-6*binomial(-n-1,k) + 7*sum(j=0,k+1, (-1)^j * (k-j+1)^(-n) * binomial(-n+1,j)))*x^k)) * x / (7*(1-x)^(-n+1)) } For Mathematica: mypolylog[n_, x_] := (6*(x+1)^(-n-1) + Sum[(x^k*(-6*Binomial[-n-1, k] + 7*Sum[(-1)^j*(k-j+1)^(-n)*Binomial[-n+1, j], {j, 0, k+1}])), {k, 0, -n-1}]) / (7*(1 - x)^(-n+1)) * x

If $a+b+c$ divides the product abc, then is (a,b,c) a Pythagorean Triple?

Firstly, I will define what Pythagorean Triples are for those who do not know. Definition: A Pythagorean Triple is a group of three integers a, b and c such that $a^2+b^2=c^2$, since the Pythagorean Theorem asserts that for any 90° (right-angle) triangle ABC with sides a, b and c, one will always have the equation, $a^2+b^2=c^2$. I was looking at Pythagorean Triples and noticed another property apart from how $a^2+b^2=c^2$. Here are the first 30 Pythagorean Triples (a,b,c) ordered from smallest to greatest value, i.e. $$(a,b,c)\qquad\text{ s.t. }\qquad a<b<c.\tag*{$\big(\text{s.t. = such that}\big)$}$$ I noticed that $a^2=(c+b)(c-b)$, but that is trivial since $$\begin{align}a^2&=(c+b)(c-b)\tag{given} \\ &=c^2-b^2 \\ \Leftrightarrow\,\,\,\, a^2+b^2&=c^2.\end{align}$$ However, I also noticed that by having "$u\mid v$" be read as "u divides v", it appears that $$a+b+c\mid abc.$$ For example, $(a,b,c)=(3,4,5)$ is a classic Pythagorean Triple; $3^2+4^2=5^2$. Also, $$\begin{align}3+4+5&=12 \\ \& \quad3\times 4\times 5 &= 60. \\ \\ 12 &\,\mid 60 \\ \Leftrightarrow \,\,\,\,\,3+4+5&\,\mid 3\times 4\times 5.\end{align}$$ This, I cannot prove to be true $-$ but I tested with all the 30 Pythagorean Triples above, and I have come across no counter-example. Is there a proof? I do not know where to begin myself. Conjecture: Given three positive integers a, b and c, if $a < b<c$ and $a^2+b^2=c^2$, then $$a+b+c\mid abc.$$ Thank you in advance. Edit: My conjecture was originally the other way round; i.e. if $a+b+c\mid abc$ then $a^2+b^2=c^2$. But 6 is a counter-example, namely because it is a Perfect Number.

Two sequences which have an average tend to zero

Let $(a_n)_{n\geq 1}, (b_n)_{n\geq 1}$ be two sequence of positive real numbers such that $$ \lim_{n\to +\infty}\frac{a_1+a_2+\cdots+a_n}{n}=\lim_{n\to +\infty}\frac{b_1+b_2+\cdots+b_n}{n}=0.$$ Conjecture. For all $\epsilon>0$, there are infinitely many values of indices k such that $a_k<\epsilon$ and $b_k<\epsilon.$ I think that this is true but I can not prove it now. In the special case where $a_n = b_n$, that is, there is only one sequence, then one can argue easily using a contradiction argument. In the general case, the hard part is to show that the same set of indices are shared by both sequences $(a_n)_{n\geq 1}, (b_n)_{n\geq 1}$.

The equation $\varphi(n)=n-\log_2(1+\operatorname{gpf}(n))-\operatorname{gpf}(n)+1$ and Mersenne primes

Let $n\geq 1$ an integer, we denote the Euler's totient function as $\varphi(n)$ and the greatest prime dividing n as $\operatorname{gpf}(n)$ (that it the arithmetic function defined in the MathWorld's article Greatest Prime Factor). I know that is it possible to prove the following claim (I was inspired in [1] to ask a similar question). Claim. If n is an integer of the form $n=p\cdot(2^p-1)$, where 2^p-1 is a Mersenne prime, then satisfies $$\varphi(n)=n-\log_2(1+\operatorname{gpf}(n))-\operatorname{gpf}(n)+1.\tag{1}$$ In this post I ask about if those are the only solutions of the equation (1). Previous equation (1) can be written also as $$\left(1+\operatorname{gpf}(n)\right)\cdot 2^{\varphi(n)+\operatorname{gpf}(n)}=2^{n+1}.\tag{2}$$ Question. Prove or disprove* the following conjecture: If an integer $N\geq 1$ satisfies our equation $$\left(1+\operatorname{gpf}(N)\right)\cdot 2^{\varphi(N)+\operatorname{gpf}(N)}=2^{N+1}$$ then $N=p(2^p-1)$, where 2^p-1 is a Mersenne prime. Many thanks. *To disprove it show a counterexample. References: [1] Tripathi, A note on products of primes that differ by a fixed integer, The Fibonacci Quarterly, Vol. 48, No. 2 (MAY, 2010).

Prove that $\sum\limits_{i=1}^{n} a_i\geq n^2$.

A hint can be helpful, but not a whole solution. The Problem (conjecture): Given a natural number $n \geq 1$ and a sequence of natural numbers $(a_i)_{1 \leq i \leq n}$ in which for every pair (i,j) with $i \neq j,$ we have $$\gcd(a_i,a_j)\nmid i-j$$ prove that $\sum\limits_{i=1}^{n} a_i\geq n^2$. What I have done: During my research, I ran into this problem and I am not quite sure if it is true. It is clear if we put $a_i=n$ then the problem will be solved and the summation will be equal to n^2. I tried to solve this problem. For example, I showed that $$a_i> max(i,n-i)$$ otherwise, I can put $j=i+a_i$ or $j=i-a_i$ and considering the fact $\gcd(a_i,a_j) \mid a_i,$ then we conclude that $\gcd(a_i,a_j)\mid i-j,$ hence, $a_i> max(i,n-i)$ which means that $a_i\geq \dfrac{n} {2}$. Moreover, if $a_i\leq n$ and p are prime divisors of a_i by putting $j=i-\dfrac {a_i}{p}$ for $i\geq \dfrac {n} {2}$ and $j=i+\dfrac {a_i}{p}$ for $i\leq \dfrac {n} {2}$ we could conclude that $a_i \mid a_j$. I could go further, but it is not enough to prove the conjecture. I also tried Induction and considered that the property holds for every $n\leq k$ and then try to prove the theorem for $n= k+1$ but again, there are some issues that I could not go further.

Is ${n^2}/D(n^2) \in \mathbb{N}$, if $q^k n^2$ is an odd perfect number?

Let $x \in \mathbb{N}$, the set of positive integers. The sum of the divisors of x is denoted by $\sigma(x)$. Denote the deficiency of x by $D(x):=2x-\sigma(x)$, and the sum of the aliquot parts of x by $s(x):=\sigma(x)-x$. Finally, denote the abundancy index of x by $I(x):=\sigma(x)/x$. If m is odd and $\sigma(m)=2m$, then m is called an odd perfect number. Euler proved that an odd perfect number (if one exists) must have the form $m=q^k n^2$ where q is the special / Euler prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Here is my question: Is ${n^2}/D(n^2) \in \mathbb{N}$, if $q^k n^2$ is an odd perfect number? MY ATTEMPT From the fundamental equality $$\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}$$ one can derive $$\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}=\gcd(n^2,\sigma(n^2))$$ so that we ultimately have $$\frac{D(n^2)}{s(q^k)}=\frac{2s(n^2)}{D(q^k)}=\gcd(n^2,\sigma(n^2)).$$ Thus, we have $$y:=\frac{n^2}{D(n^2)}=\frac{{n^2}}{s(q^k)\gcd(n^2,\sigma(n^2))}=\frac{{n^2}D(q^k)}{2s(q^k)s(n^2)}.$$ In particular, we obtain $$\frac{n^2}{D(n^2)}=\frac{{n^2}}{s(q^k)\gcd(n^2,\sigma(n^2))}=\frac{\sigma(q^k)}{2s(q^k)}.$$ Using the reasoning in this blog post, we obtain $$\frac{q}{2} + \frac{1}{2{q^{k-1}}} - \frac{1}{2q^k} < y \leq \frac{q}{2} + \frac{1}{2{q^{k-1}}}.$$ Equality holds if and only if $k=1$. That is, it appears that $y \in \mathbb{N}$ if and only if $k=1$ (i.e., the Descartes-Frenicle-Sorli conjecture holds). So the question "Is ${n^2}/D(n^2) \in \mathbb{N}$?" is equivalent to asking whether $k=1$, for $m=q^k n^2$ an odd perfect number with special / Euler prime q.

Conjecture about special grid of numbers

Consider you have created grid of numbers like following image starting from any positive integer (in this case 8) To create such grid, follow this steps; Pick a number greater than one and write down $n, n-1, n-2, ..., 1$ as column headers Likewise, write down $n, n-1, n-2, ..., 1$ as row headers Fill each cell with $row_header * column_header$ If you group numbers diagonally starting from upper left, you get these groups of numbers {64} {56, 56} {48, 49, 48} {40, 42, 42, 40} etc. Let G_n denote nth group. I want to prove if following theory is correct. $$ i < k \Rightarrow\forall x \in G_i, \forall y \in G_k, x > y $$ It seems to hold for small enough starting numbers like 8. It is trival to prove that any cell will be bigger then the cells to the right on the same row and will be bigger then the cells below it on the same column. But, I can't be sure about diagonal groups.

Show that $\int_0^1 4 \space\operatorname{li}(x)^3 \space (x-1) \space x^{-3} dx = \zeta(3) $

My mentor tommy1729 wrote $\int_0^1 4 \space \operatorname{li}(x)^3 \space (x-1) \space x^{-3} dx = \zeta(3) $ I wanted to prove it thus I looked at some methods for computing integrals and also representations of $\zeta(3)$ that might be useful. But nothing was very helpful to me. In particular the fact that the RHS is so short - Just Apery’s constant - was surprising. I expected it longer and more complicated. So I tend to believe that either the

integral computation requires many steps and Then Finally we Get a long expression but alot of cancellation until we are left with Apery’s constant only. Or There is a simple way to get Apery’s constant directly with a trick I missed. In either case it is amazing I would say. So How to show that $$\int_0^1 4 \space \operatorname{li}(x)^3 \space (x-1) \space x^{-3} dx = \zeta(3) $$ I would like to see different ways to show it. I assume real analysis methods are simpler than complex analysis methods (on the complex plane like contour integration). I Also wondered If not knowing the RHS in advance would change the difficulty of this question. Also I wonder about $$ \int_0^1 5 \space \operatorname{li}(x)^4 \space (x-1) \space x^{-4} dx = ?? $$

On the quantity ${n^2}/D(n^2)$ where n^2 is the non-Euler part of members of the OEIS sequence A228059

Let $\sigma(x)$ denote the sum of the divisors of the number $x \in \mathbb{N}$, the set of positive integers. Denote the deficiency of x as $D(x):=2x-\sigma(x)$. This afternoon I noticed some interesting fact about the quantity ${n^2}/D(n^2)$ where n^2 is the non-Euler (i.e., square) part of members of the OEIS sequence A228059. Specifically, we have the following values of n^2 from members of OEIS sequence A228059 and the corresponding (apparently almost increasing, and non-integral) values of ${n^2}/D(n^2)$: $${n_1}^2 = 3^2 = 9, {{n_1}^2}/D({n_1}^2) = 9/5 = 1.8$$ $${n_2}^2 = 3^4 = 81, {{n_2}^2}/D({n_2}^2) = {81}/{41} \approx 1.97561$$ $${n_3}^2 = {21}^2 = 441, {{n_3}^2}/D({n_3}^2) = {147}/{47} \approx 3.12766$$ $${n_4}^2 = {45}^2 = 2025, {{n_4}^2}/D({n_4}^2) = {2025}/{299} \approx 6.77258$$ $${n_5}^2 = {135}^2 = 18225, {{n_5}^2}/D({n_5}^2) = {18225}/{2567} \approx 7.09973$$ $${n_6}^2 = {285}^2 = 81225, {{n_6}^2}/D({n_6}^2) = {27075}/{2969} \approx 9.11923$$ $${n_7}^2 = {165}^2 = 27225, {{n_7}^2}/D({n_7}^2) = {27225}/{851} \approx 31.9918$$ $${n_8}^2 = {765}^2 = 585225, {{n_8}^2}/D({n_8}^2) = {585225}/{18893} \approx 30.9758$$ $${n_9}^2 = {7695}^2 = 59213025, {{n_9}^2}/D({n_9}^2) = {19737675}/{731333} \approx 26.9886.$$ Here is my question: Is it always the case that ${n^2}/D(n^2)$ is non-integral where n^2 is the non-Euler (i.e., square) part of members of the OEIS sequence A228059? Updated August 28 2018 The short answer to my original question is NO. (See the answer below.) I ask because it is known that the exponent of the special / Euler prime of an odd perfect number is 1 if and only if the non-Euler part is deficient-perfect. Coincidentally, in OEIS sequence A228059, all of the special / Euler primes for the first 9 terms have exponent 1.

Positive integers have the form $a^2+b^2+c^2+2^d$

For any positive integer n there seems to be non-negative integers a,b,c,d such that $$n=a^2+b^2+c^2+2^d.$$ Due to Legendre's three-square theorem a natural number can be represented as the sum of three squares of integers $$m=a^2+b^2+c^2$$ if and only if m is not of the form $m=4^a(8b+7)$, for integers a and b. If the conjecture is true, then for all $n\geq 1$ it must exist a k such that $n-2^k$ is not of the form $m=4^a(8b+7)$. I want help to prove the conjecture or to find a counter-example.

Question about a result on odd perfect numbers

In the paper titled Improving the Chen and Chen result for odd perfect numbers (Lemma 8, page 7), Broughan et al. show that if $$\frac{\sigma(n^2)}{q^k}$$ is a square, where $\sigma(x)$ is the sum of divisors of $x \in \mathbb{N}$ and $q^k n^2$ is an odd perfect number with special/Euler prime q, then $k=1$. Is it then possible to derive the implication $$D(n^2) = 2n^2 - \sigma(n^2) \text{ is a square } \implies k=1?$$ I could only derive the equation $$\frac{\sigma(n^2)}{q^k} = \frac{D(n^2)}{s(q^k)}$$ where $s(q^k) = \sigma(q^k) - q^k = \sigma(q^{k-1})$. Added August 25 2018 I also currently know that $$D(n^2) \mid n^2 \iff k=1.$$ That is, the Descartes-Frenicle-Sorli conjecture is true for the odd perfect number $q^k n^2$ if and only if the non-Euler factor n^2 is deficient-perfect. Added July 07 2019 If $$\frac{\sigma(n^2)}{q^k}=\frac{D(n^2)}{s(q^k)}$$ is a square, then by Broughan et al.'s result, we have $k=1$, which implies that $$s(q^k) = \sigma(q^k) - q^k = \sigma(q) - q = (q+1) - q = 1$$ is a square. Consequently, if $\sigma(n^2)/q^k$ is a square, then $D(n^2)$ is a square too.

Free action of finite cyclic group on S^3

I'm starting to read Allen Hatcher's Space of Knots and at the end of the first paragraph he says that his work would apply to all knots if the following conjecture is true: Every free action of a finite cyclic group on S^3 is equivalent to a standard linear action. The paper is from 1999, so I don't know if this is still a conjecture. Where can I read about it and the progress on it? I'm also interested in knowing how this conjecture applies to knot theory, in particular to the results Hatcher gives in the paper.

Is there are similar conjecture like this??

Talking with my friend, my friend suggest impressive conjecture that For $i\in\mathbb{N}$, there are always exist natural number r that satisfies $$\sum_{n=1}^{i} \frac{1}{n^r}=\frac{p}{q} , \gcd(p,q)=1$$ and $p+q$ is a prime number. For example, $$\sum_{n=1}^{2} \frac{1}{n}=\frac{3}{2}$$ and $3+2=5$. And $i=3$, $$\sum_{n=1}^{3} \frac{1}{n^4}=\frac{1393}{1296}$$ and $1393+1296=2689$. $$\sum_{n=1}^{4} \frac{1}{n^2}=\frac{205}{144}$$ and $205+144=349$ which is 70th prime number. In $i=5$ $$\sum_{n=1}^{5} \frac{1}{n^3}=\frac{256103}{216000}$$ and $256103+216000=472103$. Also $$\sum_{n=1}^{6} \frac{1}{n^3}=\frac{28567}{24000}$$ and $24000+28567=52567$. There are similer like this? If not, What about your think, is it true? Or false.... I would glad you guys to think about this thing and share opinions for me and my friend's curiosity. Note: ID:metamorphy suggest that the sequence of the smallest values of r begins with $1, 1, 1, 1, 1, 2, 1, 3, 1, 1, 1, 2, 34, 1, 1, 5, \ldots$. (There are full comment in bellow with more comments.)

Manufacturing desired planks from an existing pile of planks

Suppose there is a pile of commensurable planks that only may differ in lengths $0<a_1\leq\cdots\leq a_m$, which are to be used to manufacture planks of length: $0<b_1\leq\cdots\leq b_n$. Algorithm: A is the list of existent planks B is the list of wanted planks If B is empty return 'success' If $a_m<b_1$ return 'failure' Remove the smallest plank $a_i\geq b_1$ from list A Manufacture the greatest plank $b_j\leq a_i$ by, if necessary, cut a_i into planks of length b_j and $a^\prime_i$ Return what's left ($a^\prime_i$) to A Remove b_j from the list B Goto 1. I conjecture that this algorithm is optimal in two ways: If the manufacturing is possible in any way, it is also possible by the algorithm. The square sum of the lengths of the remaining planks in A is maximal compared to other cuttings. Is this possible to prove or disprove?

What is the common (and simplified) value for $D(q^k)D(n^2) = 2s(q^k)s(n^2)$ when $q^k n^2$ is an odd perfect number?

In an answer to an earlier question, it is shown that $$D(2^p - 1)D(2^{p-1}) = 2s(2^p - 1)s(2^{p-1}) = 2^p - 2,$$ if $2^{p-1}(2^p - 1)$ is an even perfect number, $D(x) = 2x - \sigma(x)$ is the deficiency of x, $s(x) = \sigma(x) - x$ is the sum of the aliquot divisors of x, and $\sigma(x)$ is the sum of divisors of $x \in \mathbb{N}$, the set of positive integers. (Lastly, denote the abundancy index of x by $I(x) = \sigma(x)/x$.) Here is my question in this post: What is the common (and simplified) value for $D(q^k)D(n^2) = 2s(q^k)s(n^2)$ when $q^k n^2$ is an odd perfect number? MOTIVATION Since $\gcd(q^k, \sigma(q^k)) = 1$, we have $$\frac{\sigma(n^2)}{q^k} = \frac{2n^2}{\sigma(q^k)} = \gcd(n^2, \sigma(n^2))$$ $$\frac{D(n^2)}{s(q^k)} = \frac{2s(n^2)}{D(q^k)} = \gcd(n^2, \sigma(n^2))$$ $$D(q^k)D(n^2) = 2s(q^k)s(n^2) = D(q^k)s(q^k)\gcd(n^2, \sigma(n^2)).$$ Then, we have from this earlier question the following expression for $\gcd(n^2, \sigma(n^2)$ in terms of q, k, n^2, and $\sigma(n^2)$: $$\gcd(n^2,\sigma(n^2)) = \frac{I(q^k)}{s(q^k)}\sigma(n^2) - \frac{1}{I(q^k)s(q^k)}(2n^2).$$ Plugging in this value for $\gcd(n^2, \sigma(n^2))$ into our equation for $$D(q^k)D(n^2) = 2s(q^k)s(n^2) = D(q^k)s(q^k)\gcd(n^2, \sigma(n^2)),$$ we obtain $$D(q^k)D(n^2) = 2s(q^k)s(n^2) = D(q^k)s(q^k)\Bigg(\frac{I(q^k)}{s(q^k)}\sigma(n^2) - \frac{1}{I(q^k)s(q^k)}(2n^2)\Bigg) = D(q^k)\Bigg(I(q^k)\sigma(n^2) - \frac{1}{I(q^k)}(2n^2)\Bigg).$$ Note that "if" $I(q^k) = -1$ then the equation would be trivial and the common value would just be $D(q^k)D(n^2)$. But, of course, we know that $$1 < I(q^k) < \frac{5}{4}.$$ Alas, this is where I get stuck.

Number of subsets of U whose arithmetic mean is integral

Question is :- n is a positive integer. Call a non-empty subset S of $\{1,2,\dots,n\}$ "good" if the arithmetic mean of elements of S is also an integer. Further Let t_n denote the number of good subsets of $\{1,2,3,\ldots,n\}$. Prove that t_n and n are both odd or both even. And my solution to this problem is :- We deal with problem in 2 cases : n is even and other when n is odd. If n is odd , we first calculate n={1,2} by brute force. We get numbers of solutions for n=1 as 1 & n=3 as 5. Thus we conjecture that t_n=$t_{n-2}+2(n-1)$ for n as even. So by this recurrence we calculate t_5 which comes to be 15. A brute force manual calculation confirms this answer . Thus we prove our conjecture by induction. Now t_1 is odd (=1) so t_2 has to be odd since t_2=$t_1+2(3-1)$,here t_1 is odd & other term is even thus overall parity is odd. So t_2 is odd. Again t_3 has to be odd as t_3=t_2+2(3-1), t_2 is odd & other term even , so t_3 is odd. So , inductively we conclude that t_n has to be odd . For the other case we conjecture same recurrence relation and prove in the same way.

Calculating the $\sum_{x=1}^\infty\left[\prod_{k=0}^s{s\choose k}x^k\right]^{-1}$

Question: If $s \in \mathbb{N}$ is it true: $\sum_{x=1}^\infty\left[\prod_{k=0}^s{s\choose k}x^k\right]^{-1}={\zeta\left[{s+1 \choose 2}\right] \above 1.5pt \prod_{k=1}^s{s \choose k}};$ where $\zeta\left[{s+1 \choose 2}\right]$ is the Riemann zeta function^1 evaluated at the triangular numbers^2 ? I believe I can show the answer to the question is yes by way of inspection. I cannot get an actual explicit calculation that answers the question affirmatively - that is what I am asking for ! Solution to question by inspection: For short handedness I write $$\zeta_{\times}(s)=\sum_{x=1}^\infty\Bigg[\prod_{k=0}^s{s\choose k}x^k\Bigg]^{-1}$$ I computed a small list of values of $\zeta_{\times}(s)$ for small s: \begin{array}{ l | l } s & 2 & 3 & 4 & 5 & 6 & 7\\ \hline \zeta_{\times}(s) & \frac{\zeta(3)}{2} & \frac{\zeta(6)}{9} & \frac{\zeta(10)}{96} & \frac{\zeta(15)}{2500} & \frac{\zeta(21)}{162000}& \frac{\zeta(28)}{26471025}\\ \end{array} Inspection suggests that $\zeta_{\times}(s)$ has numerator equal to the Riemann zeta function at ${s+1 \choose 2}.$ The denominators of $\zeta_{\times}(s)$ can be written explicitly as $2,9,96,2500,162000,\ldots$; which appear to be the integer sequence A001142^3. Listed in the reference section is the following paper by Lagarias: Products of Binomial Coefficients

and Unreduced Farey Fractions.^{4}. Lagarias defines the unreduced Farey fractions^5 to be the ordered sequence of all reduced and unreduced fractions between 0 and 1 with denominator of size at most $s.$ Following Lagarias' notation: I write G_s for the set of unreduced Farey fractions and let $|G_s|$ and G_s^* denote the cardinality and the product of all elements of G_s respectively. Lagarias shows the following results: $|G_s|={s+1 \choose 2}$ and $G_s^*=\prod_{k=1}^s{s \choose k}.$ I put everything together and get $$\zeta_{\times}(s)={\zeta\big(|G_s|\big) \above 1.5pt G_s^*}$$ and I am done. $\blacksquare$ Source and motivation of the problem: Curiosity is the main driving source of the problem. Here it goes: If x and s are positive numbers I write $\zeta(s)$ for the Riemann zeta function evaluated at the number $s.$ For ease of typing I write Pascal's Triangle^{6} like this: $$\text{ }\begin{matrix} 1&&&&\\ 1&1&&&\\ \color{red}{1}&\color{red}{2}&\color{red}{1}&&\\ \color{blue}{1}&\color{blue}{3}&\color{blue}{3}&\color{blue}{1}&\\ 1&4&6&4&1\\ \vdots \end{matrix}$$ and recall that the first row in Pascal's triangle is numbered at 0. Now look at the second and third rows of the triangle, highlighted in red and blue respectively and observe: $\sum_{x=0}^\infty{ 1 \above 1.5pt \color{red}{1}+\color{red}{2}x+\color{red}{1}x^2}=\zeta(2)$ and $\sum_{x=0}^\infty{ 1 \above 1.5pt \color{blue}{1}+\color{blue}{3}x+\color{blue}{3}x^2+\color{blue}{1}x^3}=\zeta(3).$ This observation shows that $\zeta(s)$ can be recovered from the rows of Pascal's triangle - in particular I can write $\sum_{x=0}^\infty\frac{1}{(1+x)^s}=\zeta(s).$ On the other hand using the binomial theorem^{7} allows me to compute $(1+n)^s$ explicitly with the formula: $\sum_{k=0}^s{s\choose k}x^k$ in which case after substitution: $$\zeta(s)=\sum_{x=0}^\infty\bigg[\sum_{k=0}^s{s\choose k}x^k\bigg]^{-1}$$ Now out of total curiosity I decided to swap the inner summation inside the big brackets and swap it out with a product, noting carefully that if I do that I need to shift the starting point in the outer summation to 1 otherwise I would be dividing by zero. For short handedness I wrote $$\zeta_{\times}(s)=\sum_{x=1}^\infty\Bigg[\prod_{k=0}^s{s\choose k}x^k\Bigg]^{-1}$$ Numerical inspection suggested $$\zeta_{\times}(s) ={\zeta\left[{s+1 \choose 2}\right] \above 1.5pt \prod_{k=1}^s{s \choose k}}$$ I double checked my numerical hunch against Sloan's Database and encountered the paper by Lagarias. In Lieu of the fact that Lagarias has an explicit formulae for $\log G_s^*$ (see Lagarias paper or reference above for notation) I primarily became interested in computing $\log \zeta_{\times}(s).$ If I could answer the question affirmatively then I would know that $$\log \zeta_{\times}(s)=\log \zeta(|G_s|)-\log(G_s^*)$$

Conjecture for $\ln(x)$ and $\frac{d^ny}{dx^n}$

I'm not really sure where to start, I found the first, second, third and fourth derivatives of $\ln(x)$ to be $\frac{1}{x}$,-$\frac{1}{x^2}$, $\frac{2}{x^3}$, and -$\frac{6}{x^4}$, respectively. Letting n be a natural number, I have to formulate a conjecture for a formula for $\frac{d^ny}{dx^n}$. Afterward, I have to use mathematical induction to prove the conjecture.

Validation for a conjecture about Chinese Remainder Theorem for groups

I was wondering if the following statement is true: Let G be a group with normal subgroups $H_1,H_2,...H_n$. Suppose $H_iH_j=G$ for all $i\neq j$. Then $G/H_1\cap H_2...\cap H_n\cong G/H_1 \times...\times G/H_n.$ There is a similar question here, which is the case when $n=2$. There is also a similar question here, but the conditions involve the index of a subgroup. I want to get rid of such condition so that the conclusion is applicable to some other situations. But when I tried to proceed proof by induction to get the conclusion with arbitrary n, things became not so approachable. If you think this is false, please give a counter-example. If you think this is true, please share your ideas of the proof. Thank you!

Schwarz inequality for unital positive maps on C*-algebras

I was recently studying this paper by Man-Duen Choi about inequalities for positive maps on C*-algebras. He demonstrates that Let $\phi : \mathcal{A} \to \mathcal{B}$ be a unital positive linear map between the two C*-algebras $\mathcal{A}, \mathcal{B}$. Then $$ \phi(A^* A) \ge \phi(A)^* \, \phi(A) $$ and $$ \phi(A^* A) \ge \phi(A) \, \phi(A)^* $$ for every subnormal $A \in \mathcal{A}$. He then conjectures that the same result might apply also for hyponormal opertators, i.e. operators such that $A^* A \ge A A^*$ (this conjecture is equivalent to the Woronowicz's conjecture). I was wondering whether this conjecture has been better investigated or not. Also, is there a characterization of hyponormal operators?

Does mathlove's answer imply that $D(n^2) \mid n^2$?

In what follows, set $\sigma(x)$ to be the sum of divisors of $x \in \mathbb{N}$, and let $$D(x) = 2x - \sigma(x)$$ be the deficiency of x, and let $$s(x) = \sigma(x) - x$$ be the sum of the aliquot divisors of x. An earlier question asks: What is the common (and

simplified) value for $D(q^k)D(n^2) = 2s(q^k)s(n^2)$ when $q^k n^2$ is an odd perfect number? In the accepted answer, MSE user mathlove writes: $$\begin{align}D(q^k)D(n^2) &= 2s(q^k)s(n^2) \\\&=\frac{2n^2(q^k-1)(q^{k+1}-2q^k+1)}{(q-1)(q^{k+1}-1)}\end{align}.$$ Now, I know that $$s(q^k) = \sigma(q^k) - q^k = \sigma(q^{k-1}) = \frac{q^k - 1}{q - 1}$$ and that $$\gcd(D(q^k), s(q^k)) = 1.$$ Here is my question in this post: Does mathlove's answer imply that $D(n^2) \mid n^2$? I ask because the divisibility condition $D(n^2) \mid n^2$ for the non-Euler part n^2 is known to be equivalent to the Descartes-Frenicle-Sorli Conjecture (that is, $k=1$) for odd perfect numbers.

Can this bound for the abundancy index of n be improved, given that $q^k n^2$ is an odd perfect number with $k=1$?

In what follows, set $I(x)=\sigma(x)/x$ to be the abundancy index of $x \in \mathbb{N}$, where $\sigma(x)$ is the sum of divisors of x. If $I(y)=2$ and y is odd, then y is called an odd perfect number. Euler proved that an odd perfect number, if one exists, must have the so-called Eulerian form $N = q^k n^2$ where q is the special/Euler prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. The following result was communicated to me (via e-mail, by Pascal Ochem) on April 17, 2013. If $N = {q^k}{n^2}$ is an odd perfect number given in Eulerian form, then $$I(n) > {\left(\frac{8}{5}\right)}^{\frac{\ln(4/3)}{\ln(13/9)}} \approx 1.44440557.$$ The proof of this result uses the following lemma. Let $x(n) = \ln(I(n^2))/\ln(I(n))$. If $\gcd(a, b) = 1$, then $$\min(x(a), x(b)) < x(ab) < \max(x(a),x(b)).$$ Proof of Lemma: First, note that $x(a) \neq x(b)$ (since $\gcd(a , b) = 1$). Without loss of generality, we may assume that $x(a) < x(b)$. Thus, since $$x(n) = \frac{\ln(I(n^2))}{\ln(I(n))},$$ we have $$\frac{\ln(I(a^2))}{\ln(I(a))} < \frac{\ln(I(b^2))}{\ln(I(b))}.$$ This implies that $$\ln(I(a^2))\ln(I(b)) < \ln(I(b^2))\ln(I(a)).$$ Adding $\ln(I(a^2))\ln(I(a))$ to both sides of the last inequality, we get $$\ln(I(a^2))\bigg(\ln(I(b)) + \ln(I(a))\bigg) < \ln(I(a))\bigg(\ln(I(b^2)) + \ln(I(a^2))\bigg).$$ Using the identity $\ln(X) + \ln(Y) = \ln(XY)$, we can rewrite the last inequality as $$\ln(I(a^2))\ln(I(ab)) < \ln(I(a))\ln(I((ab)^2))$$ since $I(x)$ is a weakly multiplicative function of x and $\gcd(a, b) = 1$. It follows that $$\min(x(a), x(b)) = x(a) = \frac{\ln(I(a^2))}{\ln(I(a))} < \frac{\ln(I((ab)^2))}{\ln(I(ab))} = x(ab).$$ Under the same assumption $x(a) < x(b)$, we can show that $$x(ab) < x(b) = \max(x(a),x(b))$$ by adding $\ln(I(b^2))\ln(I(b))$ (instead of $\ln(I(a^2))\ln(I(a))$) to both sides of the inequality $$\ln(I(a^2))\ln(I(b)) < \ln(I(b^2))\ln(I(a)).$$ This finishes the proof. From this lemma, we note that $1 < x(n) < 2$ follows from $$I(n) < I(n^2) < {\left(I(n)\right)}^2$$ and $I(n^2) = {\left(I(n)\right)}^{x(n)}$. The trivial lower bound for $I(n)$ is $${\bigg(\frac{8}{5}\bigg)}^{1/2} < I(n).$$ Note that decreasing the denominator in the exponent gives an increase in the lower bound for $I(n)$. Proof of Result: We sketch a proof for the mentioned result here, as communicated to the author by Pascal Ochem. Suppose that $N = {q^k}{n^2}$ is an odd perfect number given in Eulerian form. We want to obtain a lower bound on $I(n)$. We know that $$I(n^2) = 2/I(q^k) > 2/(5/4) = 8/5.$$ We need to improve the trivial bound $I(n^2) < {\left(I(n)\right)}^2$. Let $x(n)$ be such that $$I(n^2) = {\bigg(I(n)\bigg)}^{x(n)}.$$ That is, $x(n) = \ln(I(n^2))/\ln(I(n))$. We want an upper bound on $x(n)$ for n odd. By the lemma, we consider the component r^s with r prime that maximizes $x(r^s)$. We have $$I(r^s) = \frac{r^{s + 1} - 1}{{r^s}(r - 1)} = 1 + \frac{1}{r - 1} - \frac{1}{{r^s}(r - 1)}.$$ Also, $$I(r^{2s}) = \frac{r^{2s + 1} - 1}{{r^{2s}}(r - 1)} = I(r^s)\bigg(1 + \left(\frac{1 - r^{-s}}{r^{s + 1} - 1}\right)\bigg).$$ So, $$x(r^s) = \frac{\ln(I(r^{2s}))}{\ln(I(r^s))} = \frac{\ln(I(r^s)) + \ln(1 + \left(\frac{1 - r^{-s}}{r^{s + 1} - 1}\right))}{\ln(I(r^s))},$$ from which it follows that $$x(r^s) = 1 + \frac{\ln(1 + \left(\frac{1 - r^{-s}}{r^{s + 1} - 1}\right))}{\ln(1 + \frac{1}{r - 1} - \frac{1}{{r^s}(r - 1)})}.$$ We can check that $$x(r^s) > x(r^t)$$ if $s < t$ and $r \geq 3$. Therefore, $x(r^s)$ is maximized for $s = 1$. Now, $$x(r) = 1 + \frac{\ln(1 + (1/(r(r + 1))))}{\ln(1 + (1/r))} = \frac{\ln(1 + (1/r) + (1/r)^2)}{\ln(1 + (1/r))} = \ln(I(r^2))/\ln(I(r)),$$ which is maximized for $r = 3$. So, $$x(3) = \ln(I(3^2))/\ln(I(3)) = \ln(13/9)/\ln(4/3) \approx 1.27823.$$ The claimed result then follows, and the proof is complete. Motivation for My Inquiry Note that, since q is prime with $q \equiv 1 \pmod 4$, then $q \geq 5$. In particular, when $k=1$, then we obtain $$I(q^k) = 1 + \frac{1}{q} \leq \frac{6}{5} \iff I(n^2) = \frac{2}{I(q^k)} \geq \frac{5}{3},$$ from which we get $$I(n) > \bigg(I(n^2)\bigg)^{1/{x(3)}} \geq \bigg(\frac{5}{3}\bigg)^{\frac{\ln(4/3)}{\ln(13/9)}} \approx 1.4912789897463723558.$$ Here is my question: Would it be possible to tweak the argument in this post in order to come up with a proof for the implication $$k=1 \implies I(n) > \frac{3}{2}?$$

If x and y are solitary numbers satisfying $\gcd(x,y)=1$, under what conditions does it follow that xy is also solitary?

Let $\sigma(z)$ denote the sum of divisors of $z \in \mathbb{N}$. Denote the abundancy index of z by $I(z) = \sigma(z)/z$. If the equation $I(z)=I(a)$ has the lone solution $z=a$, then a is said to be solitary. Greening's Theorem states that if $\gcd(b,\sigma(b))=1$, then b is solitary. (Note that the converse does not necessarily hold.) Here is my question: If x and y are solitary numbers satisfying $\gcd(x,y)=1$, under what conditions does it follow that xy is also solitary? The latest paper on solitary numbers that I could find on Google seems to be New families of solitary numbers by Paul A. Loomis. However, my present inquiry is not covered in this paper.

$\sum_i X_i^2$ has χ^2_{n} distribution and X_i i.i.d. imply X_i normal

Let $X_1,\ldots,X_n$ be i.i.d. random variables with distribution F. It is known that if F is the standard normal distribution then $$ S:=\sum_{i=1}^n X_i^2 $$ has a chi square distribution with n degrees of freedom. I remeber that the converse is an open problem: if S has a chi square distribution with n degrees of freedom then F has to be the standard normal. Do you have some references on this problem? (I remember that some instances has been solved, but I couldn't find them anymore)

A weaker conjecture than a known conjecture

I really apologize if my question is not appropriate here, though I hope it is. Let C be any known conjecture in mathematics, which is still open. Let D be another conjecture such that a positive answer to conjecture C implies a positive answer to conjecture D. Now assume that one proved conjecture D. Do you think that mathematicians working on conjecture C will find such a result interesting? Of course, if one has found a counterexample to conjecture D, then conjecture C is false, but this is not the situation I am asking about. Thank you very much!

The sum of all divisors of N is a 2 potency iff N is a product of different Mersenne primes

As far as I have controlled: $\sigma(a)=2^n$, for some $n\in\mathbb N \iff $ a is a product of different Mersenne primes. The $\Leftarrow$-part is an immediate consequence of that σ is multiplicative, but the other part seems more complicated, if it is true. Maybe this is interesting in the view of that it is unknown if there are only a finite number of Mersenne primes or not.

What proportion of the positive integers satisfies $\gcd(n^2,\sigma(n^2))>\sigma(n)$, where σ is the sum-of-divisors function?

The title says it all. What proportion of the positive integers satisfies $\gcd(n^2,\sigma(n^2))>\sigma(n)$, where σ is the sum-of-divisors function? I tried using Sage Cell Server to search for positive integers n satisfying the said inequality, in the range $1 \leq n \leq {10}^6$, but it was unable to find any. I dare to conjecture that the proportion in question is zero, but I have no proof. Updated November 28 2018 I got the same output as Julian, after running the following (presumably correct) GP code in Sage Cell Server: for (x=1, 1000000,if(gcd(x^2,sigma(x^2))>sigma(x),print(x))) Updated November 29 2018 The number $n=1$ satisfies $$\gcd(n^2,\sigma(n^2))=\sigma(n)$$ while almost all integers $n>1$ (except for the 111 numbers less than ${10}^6$ mentioned by Julian in his answer below) satisfy $$\gcd(n^2,\sigma(n^2))<\sigma(n).$$ Therefore, I think it might indeed be possible to prove that the set $$\bigg\{n \in \mathbb{N} \mid \gcd(n^2,\sigma(n^2)) > \sigma(n)\bigg\}$$ has asymptotic density 0. But then again, as I have already mentioned, I have no proof.

For all $n>1$ there are positive $a+b=n$ such that $a+ab+b\in\mathbb P$

For all integers $n>1$ there are positive integers a,b such that $a+b=n$ and such that $a+ab+b\in\mathbb P$. Tested for all $n\leq 1,000,000$. Hopefully, someone can explore and explain the heuristics about this conjecture. This question is related to: Any odd number is of form $a+b$ where a^2+b^2 is prime Does every power of two arise as the difference of two primes? Most even numbers is a sum $a+b+c+d$ where $a^2+b^2+c^2=d^2$ Natural numbers large enough can be written as $ab+ac+bc$ for some $a,b,c>0$ $\{a+b|a,b\in\mathbb N^+\wedge ma^2+nb^2\in\mathbb P\}=\{k>1|\gcd(k,m+n)=1\}$ Even numbers has the form $a+b$ where $\frac{a^2+b^2}{2}$ is prime Is every positive integer greater than 2 the sum of a prime and two squares? It's about a relation $R\subseteq \mathbb N^m$, a function $f:\mathbb N^m\to \mathbb N$, and an image of a restriction $\operatorname{Im}(f|R)$. In Goldbachs conjecture the relation is $p,q\in\mathbb P$, the function is $(p,q)\mapsto p+q$ and the image of the restriction is $2\mathbb N\setminus\{2\}$. Maybe some of the conjectures can be generalized?

Every 'decreasing' or 'increasing' infinite sequence whose sum converges contains at least one term of magnitude 0

Note on the title: This conjecture is not restricted to real numbers, 'decreasing' and 'increasing' were used because of the character limit. The actual conjecture is that every sequence whose terms strictly increase or decrease in magnitude contains at least one term whose magnitude is 0. Warning: the following contains a gratuitous excess of '∞' it is recommended that you be familiar with at least one of the following: extended real/complex numbers (projective real, hypereal, Riemann sphere, etc.), non-standard numbers, or "Indian" infinities (Jaina infinities, Bhaskara, etc.). Let $\mathbb{U}$ denote a universe (e.g. $\mathbb{R}^n,\mathbb{C},\mathbb{H}\setminus\mathbb{R},\ldots$ etc.), where $u\in\mathbb{U}\implies |u|\neq\infty$ Definition: finite - a number* $z\in\mathbb{U}$ is finite iff $|z|\in(0,\infty)$ Definition: infinitesimal - a number $z\in\mathbb{U}$ is infinitesimal iff $\forall w\in\mathbb{U}\setminus\{\mathbb{U}_0\}.|z|<|w|$, where $\mathbb{U_0}$ is the additive identity (zero) of $\mathbb{U}$ Definition: infinite - a number $z\in\mathbb{U}$ is infinite iff $\forall w\in\mathbb{U}.|z|>|w|$ Definition: convergence - the sum of an infinite sequence $A\subseteq \mathbb{U}$ converges iff $\sum A\in\mathbb{U}$ Let A be an infinite sequence in $\mathbb{U}$, indexed by a set $I\subseteq\mathbb{N}\cup\{\infty\}$ where: $$A=\bigcup_{i\in I}\{a_i\}:\qquad\forall i,j\in I.i<j\implies(|a_i|\leq|a_j|\oplus |a_i|\geq|a_j|)$$ and where $\lim_{i\to n}a_i=a_n$, i.e. A is equal to its own limit at every point and is strictly increasing xor decreasing in magnitude. Conjecture: $$\sum_{i\in I}a_i\in\mathbb{U}\implies\exists k\in I:|a_k|=0$$ Reasoning: The sum of infinitely many finite numbers is always infinite (proof needed). Thus, if A contains only finite terms, then the sum of A does not converge. If a_1 is finite and A is increasing, then either all $a\in A$ are finite, or $|a_\infty|=\infty$. In the case of the former, $\sum A$ is the sum of infinitely many finite terms, and thus infinite. In the case of the latter, A contains at least one infinite term, therefore $|\sum A|=|a_1|+\cdots+\infty=\infty$. This is intuitively reinforced (though not proven) by treating the sum of A as the integral of a continuous function.** If A is increasing and the sum of A converges, then the first term must be infinitesimal. Since the magnitude of a number is given by a standard, real number, it follows that $|a_1|=0$. If A is decreasing and the sum of A converges, then $|a_\infty|=0$. Otherwise, $|a_\infty|$ is finite, making all $a\in A$ finite; if this were the case, then sum of A would be the sum of A would not converge. While this is at least true for all integer sequences (unless there is a proof that the sum of an infinite sequence of increasing integers converges), I'm not absolutely certain that it holds for all sequences. If it does, the how should I prove this? Can I prove this? I'm particularly skeptical about what would happen if I applied this to sequences of matrices or to sequenences with multiple infinite terms (e.g. where $|a_1|=|a_\infty|=\infty$ but $|a_1+a_\infty|=0$) *the term "number" can be replaced with "element" as this can also apply to the elements of any $\mathbb{U}$ equipped with a unary operation $|\cdot|:\mathbb{U}\to\mathbb{R}\cup\{\infty\}$ for which $u\in\mathbb{U}\implies|u|\neq\infty$ **Imagine a function $f:\mathbb{R}\to\mathbb{U}$ such that $n\in\mathbb{N}\implies f(n)=a_n$ and $\forall x,y,z\in\mathbb{R}. x<y<z\implies |f(x)|\leq|f(y)|\leq|f(z)|$. For any such function $\int_0^\infty f(x)\ dx=\infty$, even if $f(\infty)$ is finite (proof needed). This is actually one way to show that $\int\frac{1}{z}\ dx=\ln{z}$.

On an interesting assertion in the OeisWiki page on multiply-perfect numbers

The following (interesting) assertion appears in the OeisWiki page on multiply-perfect numbers: ---------- Forwarded message ---------- From: Georgi Guninski <guninski@guninski.com> To: Sequence Fanatics Discussion list <seqfan@list.seqfan.eu> Cc: Date: Mon, 16 Jul 2012 13:14:33 +0300 Subject: [seqfan] Re: Reference that "A027687 4-perfect numbers" is finite Thank you. Asked because an odd perfect number and infinitely mersenne primes implies 4-perfect numbers are infinite (and a lot of other 2k-perfect numbers) - take the product of the OPN and coprime to it EPN. On the other hand 4-perfect being finite and infinitely mersenne primes implies no OPN. What is the reason to believe all 4-perfect are discovered (even if they are finite)? (This post is taken from the following SeqFan thread.) Honestly, I cannot seem to wrap my head around the first assertion (and therefore, also the second). Why is it that the existence of an odd perfect number and infinitely many Mersenne primes implies that there are infinitely many 4-perfect numbers (and a lot of other $2k$-perfect numbers)? It says "take the product of the OPN and coprime to it EPN". However, an OPN and an EPN may not always be coprime, as a Mersenne prime (for example, 3) may divide an OPN. (See this MSE question.) Note: OPN = Odd Perfect Number, EPN = Even Perfect Number

Probability for composite n to have prime factor $\geq \sqrt n$

Let $\operatorname{GPF}(n)$ denote the largest prime factor of $n\in\mathbb N_{>1}$. My computer tests for intervalls $[m,n]$, where $n<10,000,000$, suggests that the probability $\operatorname{P}(\operatorname{GPF}(n)\geq\sqrt n)$ is asymptotically equivalent with a constant $\approx\frac{8}{11}$. Can this be proved, heuristically understood or falsified?

I have found a way of computing Euler's number. Is there any possible intuition of how that might be the case?

So a few days ago I just kind of messed around with my calculator, when I had an idea about a new continued fraction. I inputted it, and I found that it converged really quickly, and, quite wondrously, converged to the base of the natural logarithm. Then, the day later, I tried computing a similar continued fraction, this time starting with the number 2 instead of 1, without the increment of the numerator by 1. My first computation My second computation Interestingly, the second computation converges to EXACTLY the same values, except it's faster in the sense that the first method is delayed by 1 value per time. Does anybody possibly have an intuition / explanation as for why this might be the case? I've looked at the general ways of computing e: the sum of integer factorials and (1+1/n)^n, which I suspect might be more relevant to this.

What is the sufficient and necessary conditions that $-1 \in G$, where G is a multiplicative group of a ring.

I am trying to prove the following conjecture. Let $(R, +,\times)$ be a finite ring with an identity. Let G be a subgroup of $(R,\times)$ with order d. Then $-1\in G$, if and only if $2\mid d$ or $\text{Char}(R)=2$. My attempt: $\Leftarrow$: Case 1:If $\text{Char}(R)=2$, then $-1=1$. Since G is a multiplicative group, the indentity $1\in G$. Hence $-1\in G$. Case 2: If $2\mid d$, then ...(I do not know how to prove in this case.) $\Rightarrow$: Suppose that $-1 \in G$. Then $(-1)^2=1\in G$. The multiplicative order of -1 is either 2 or 1. If $\text{Ord}(-1)=1$, then $-1=1$. Consequently, $\text{Char}(R)=2$. If $\text{Ord}(-1)=2$, then it must have $\text{Ord}(-1) \mid \text{Ord}(G)$, i.e., $2\mid d$. ========== So does $2\mid d$ implies that $-1\in G$? If the conjecture does not hold, then can we have a sufficient and necessary condition of $-1 \in G$? Thanks to Arthur, we have the following result using the fact that -1 is the only element of order 2. Let $(R, +,\times)$ be an integral domain. Let G be a subgroup of $(R,\times)$ with order d. Then $-1\in G$, if and only if $2\mid d$ or $\text{Char}(R)=2$.

Conjecture about polynomials $f_n\in\mathbb Q[X_1,\dots,X_n]$ defining bijections $\mathbb N^n\to\mathbb N$

This is inspired by an answer of a question of mine: Bijective polynomials $f\in\mathbb Q[X_1,\dots,X_n]$ There is a polynomial $f_1\in\mathbb Q[X_1]$ which define a bijection $f_1:\mathbb N\to\mathbb N$, $f_1(X_1)=X_1$. There is a polynomial $f_2\in\mathbb Q[X_1,X_2]$ which define a bijection $f_2:\mathbb N^2\to\mathbb N$, $\displaystyle f_2(X_1,X_2)=\frac{(X_1+X_2)(X_1+X_2+1)}{2}+f_1(X_1)$. And as far as I understand and have tested there is a polynomial $f_3\in\mathbb Q[X_1,X_2,X_3]$ which define a bijection $f_3:\mathbb N^3\to\mathbb N$ $\displaystyle f_3(X_1,X_2,X_3)=\frac{(X_1+X_2+X_3)(X_1+X_2+X_3+1)(X_1+X_2+X_3+2)}{6}+f_2(X_1,X_2)$. This seems possible to generalize as $\displaystyle f_{n+1}(X_1,\dots ,X_{n+1})=f_{n}(X_1,\dots ,X_{n})+\frac{1}{(n+1)!}\prod_{k=1}^{n+1}\Big(k-1+\sum_{i=1}^{n+1}X_i\Big)$. This is a generalisation of the diagonalization in case of $n=2$ with "triangularization", "tetraederization" or higher. Now the conjecture is $\displaystyle f_n(X_1,\dots,X_n)$ define a bijection $\mathbb N^n\to\mathbb N$ for all $n>0$. Induction seems natural but how to prove that f_n is a bijection implies that f_{n+1} is a bijection? What I want are proofs, parts of proofs or counter proofs.

Conjecture about fixed prime divisors of polynomials with integer coefficients

While experimenting with random polynomials I've found this conjecture: A polynomial $f\in\mathbb Z[X]$ of degree n with co-prime coefficients have no fixed prime divisor $p> n$. A fixed prime divisor is a prime p such that $p|f(m)$ for all $m\in\mathbb Z$. Is this known? Proved? Or are there counterexamples?

Proof of $ x^2 + y = y^2 + x$ when $ x+ y =1$ and x is larger than y

I know that whatever numbers you choose for x and y and their sum equals to 1 will satisfy the equation $x^2 + y = y^2 + x$ Algebraic proof: Given: $x + y = 1$ $$LS = x^2+ y = (1-y)^2 + y = 1 - 2y+y^2 + y = y^2 - y + 1$$ $$RS = y^2 + x = y^2 + (1-y) = y^2 - y + 1$$ Therefore,$$ LS = RS $$ How can this be proved geometrically? (Ex. in a diagram of rectangular areas) I tried to add a square piece with side lengths y with a rectangle with side lengths x and x+y but I can't seem to prove it geometrically. Can someone help?

Can Erdős-Turán $\frac{5}{8}$ theorem be generalised that way?

Suppose for an arbitrary group word w ower the alphabet of n symbols $\mathfrak{U_w}$ is a variety of all groups G, that satisfy an identity $\forall a_1, ... , a_n \in G$ $w(a_1, ... , a_n) = e$. Is it true, that for any group word w there exists a positive real number $\epsilon (w) > 0$, such that any finite group G is in $\mathfrak{U_w}$ iff $$\frac{\lvert\{(a_1, ... , a_n) \in G^n : w(a_1, ... , a_n) = e\}\rvert}{{|G|}^n} > 1 - \epsilon(w)?$$ How did this question arise? There is a widely known theorem proved by P. Erdős and P. Turán that states: A finite group G is abelian iff $$\frac{|\{(a, b) \in G^2 : [a, b] = e\}|}{{|G|}^2} > \frac{5}{8}.$$ This theorem can be rephrased using aforementioned

terminology as $\epsilon([a, b]) = \frac{3}{8}$. There also is a generalisation of this theorem, stating that a finite group G is nilpotent of class n iff $$\frac{|\{(a_0, a_1, ... , a_n) \in G^{n + 1} : [... [[a_0, a_1], a_2]... a_n] = e\}|}{{|G|}^{n + 1}} > 1 - \frac{3}{2^{n + 2}},$$ thus making $\epsilon([... [[a_0, a_1], a_2]... a_n]) = \frac{3}{2^{n + 2}}$. However, I have never seen similar statements about other one-word varieties being proved or disproved, despite such question seeming quite natural . . . Actually, I doubt that the conjecture in the main part of question is true. However, I failed to find any counterexamples myself.

Multiplicative order of $a\bmod c^{k+1}$

I have some questions about moving from $\mathbb Z_{c^k}$ into $\mathbb Z_{c^{k+1}}$-specifically, with regard to the order of elements. Suppose a (which is coprime to c) has multiplicative order b in $\mathbb Z_{c^k}$. Now if a has multiplicative order p in $\mathbb Z_{c^{k+1}}$, then, $c^{k+1}\mid (a^p-1)\implies c^k\mid(a^p-1)\implies b\mid p$ So $p=bn$ for some positive integer n. $$\require{cancel}a^b\equiv 1\mod c^k\implies a^{bn}\equiv 1\mod c^{k+1}$$ $$(a^b)^n\equiv 1\mod c^{k+1}\implies ((a^b-1)+1)^n\equiv 1 \mod c^{k+1}$$ $$\sum_{i=0}^n\Biggl(\binom{n}{i}(a^b-1)^i1^{n-i}\Biggr)\equiv 1 \mod c^{k+1}$$ Since $c^k|(a^b-1):$ $$\binom{n}{0}(a^b-1)^01^{n-0}+\binom{n}{1}(a^b-1)^11^{n-1}+\sum_{i=2}^n\cancelto{0}{\Biggl(\binom{n}{i}(a^b-1)^i1^{n-i}\Biggr)}\equiv 1\mod c^{k+1}$$ $$1+n(a^b-1)\equiv 1\mod c^{k+1}$$ So, finally: $$n(a^b-1)\equiv 0\mod\ c^{k+1}$$ This gives us that $n|c$. More specifically, if $g.c.d.\Bigl(\frac{a^b-1}{c^k},c\Bigr)=d$, then $n=\frac{c}{d}$. Now, looking at something like the base-a Wieferich primes, there are clearly examples when $n\neq c$ (technically, Wieferich primes don't care specifically about the multiplicative order of the bases, but it happens frequently enough that $p-1$ is the base's order). I have two main questions. For any non-perfect power, c, can we always find an a and a k such that, if $ \operatorname{ord}(a)=b$ in $\mathbb Z_c$ and $ \operatorname{ord}(a)=n$ in Z_{c^k}, $n\neq bc^{k-1}$? And, second, (with c still being a non-perfect power$\neq2$) is it possible that, if, for some given a, that $ \operatorname{ord}(a)=b$ in $\mathbb Z_c$ and $ \operatorname{ord}(a)=bc$ in $\mathbb Z_{c^2}$, but for some $k>2$, $ \operatorname{ord}(a)\neq bc^{k-1}$ in $\mathbb Z_{c^k}$? Edit: I think I have an answer to the first question-it looks to be a bit more general. If we look at the set of elements in $\mathbb Z_{c^{k+1}}$ that are invertible, we have a group under the operation of multiplication- denote it by $V_{c^{k+1}}$. Of course, these are exactly the elements that are coprime to c^{k+1} so the order of this group is $$\phi(c^{k+1})=c^{k+1}\prod_{p:p=prime,p\mid c^{k+1}}\Bigl(1-\frac{1}{p}\Bigr)=c^{k+1}\prod_{p:p=prime,p\mid c}\Bigl(1-\frac{1}{p}\Bigr)=\\\frac{c^{k+1}}{\prod_{p:p=prime,p\mid c}p}\prod_{p:p=prime,p\mid c}(p-1)=d\prod_{p:p=prime,p\mid c}(p-1)$$ where d is clearly an integer. Now, consider any prime factor, q, of $p_{min}-1$ (where p_{min} is the smallest prime that divides c). $$q\mid (p_{min}-1)\mid\biggl(\prod_{p:p=prime,p\mid c}(p-1)\biggr)\mid \phi(c^{k+1})=\Bigl|V_{c^{k+1}}\Bigr|$$ So $q\mid \Bigl|V_{c^{k+1}}\Bigr|$. But by Cauchy's theorem for groups, this means that $V_{c^{k+1}}$ has an element of order q- denote it by x. Clearly the multiplicative of order of x in $\mathbb Z_{c^{k+1}}$ is also q. Referring back to the way q was defined, it's clear that q and c are coprime (since q must be less than any prime factor of c). But, if x has order b in $\mathbb Z_{c^k}$, then the order of x in $\mathbb Z_{c^{k+1}}$ is (as shown before) of the form bn where n is some divisor of c. That means $bn=q$. Since q and c are coprime, $n=1$, and $b=q$, i.e., the order of x is the same in $\mathbb Z_{c^{k+1}}$ as it is in $\mathbb Z_{c^k}$. The reason this seems more general is that it works for any k. Of course, there's a small flaw when it comes to c being even, i.e. that $p_{min}-1=2-1=1$ always. But, the above argument could still easily be extended to any even numbers where the 2^{nd} smallest prime divisor isn't a Fermat prime (just let q be some prime other than 2 that divides the second smallest prime-1). Even if the second smallest prime divisor is Fermat, we'll still have $\operatorname{ord}(a)=2b\neq bc^k$ (I just can't guarantee an element with the same order in $\mathbb Z_{c^k}$ and $\mathbb Z_{c^{k+1}}$ exists). That seems to just leave $c=2$. Still have no clue how to deal with the second question. Edit 2: The above argument (in the Edit) can be tweaked a bit- once we have an x of order q in $\mathbb Z_{c^{k+1}}$, instead of returning to $\mathbb Z_{c^k}$ and examining x's order there, we can look directly at $\mathbb Z_c$ instead. If the order of x in $\mathbb Z_c$ is b, then by extending the reasoning presented above, the order of x in $\mathbb Z_{c^{k+1}}$ is bN, where N is a divisor of c^k. That means $bN=q$ and (since q and c are coprime) $b=q$ but now b is the order of x in $\mathbb Z_c$. This reasoning can be extended so that for every $1\leq h\leq k+1$, the order of x in $\mathbb Z_{c^h}$ is the same. This seems to be suggesting that the answer to the second question is generally no- but that would be to assume that elements that do not have order bc^k in $\mathbb Z_{c^{k+1}}$ are only constructed by the method in the first Edit (it also isn't true in the case when $c=2$ just by the fact that all odd numbers have order 1 in $\mathbb Z_2$).

A conjecture about irreducible polynomials with integer coefficients

Let $f\in\mathbb Z[X]$, define $\operatorname{P}^+(f)$ as the number of primes >0 that f assumes at distinct integral arguments. Theorem: If $f\in\mathbb Z[X]$ is non constant and reducible of degree n, then $\operatorname{P}^+(f)\leq n$. And for all n there are non constant reducible polynomials of degree n such that $\operatorname{P}^+(f)=n$. [Acta Arith.,104.2 (2002) 117-127.] Most polynomials are irreducible but using the theorem for an irreducibility test would be inefficient since a lot of irreducible polynomials has a fixed divisor >1 and wouldn't pass the test. A conjecture related to the conjecture of Bunjakowsky states: Conjecture: If $ f\in\mathbb Z[X]$ is non constant and irreducible, then $f(a)/d$ assumes primes for an infinit number of distinct integral arguments a, where d is the largest fixed divisor of f. Irreducibility of Polynomials Whose Coefficients are Integers Page 32. This makes me wonder if the following hypothesis is true: $f\in\mathbb Z[X]$ of

degree $n>0$ with coprime coefficients is irreducible, iff $\;\operatorname{P}^+(d^{-1}\cdot f)> n$ or $\;\operatorname{P}^+(d^{-1}\cdot (-f))> n$, where d is the greatest fixed divisor of f. P^+ is extended above and defined even for integer-valued polynomials with rational coefficients. Proofs or counter-examples? With a test program using the hypothesis on Eisenstein polynomials f with random coefficients between -19 and 19 and random degree between 2 and 5, testing both f and $-f$, resulted in no miss in $1,000,000$ polynomials. The only drawback is the risk of overflow when evaluating the polynomials for higher degrees and greater coefficients.

On Ramanujan's Question 359

In JIMS 4, p.78, Question 359 was asked by Ramanujan. (See The Problems Submitted by Ramanujan to the Journal of the Indian Mathematical Society, p. 9, by Bruce Berndt, et al.) If, $$\sin(x+y) = 2\sin\big(\tfrac{1}{2}(x-y)\big)\tag1$$ $$\sin(y+z) = 2\sin\big(\tfrac{1}{2}(y-z)\big)\tag2$$ prove that, $$\big(\tfrac{1}{2}\sin x\cos z\big)^{1/4}+\big(\tfrac{1}{2}\cos x\sin z\big)^{1/4} =\big(\sin 2y)^{1/12}\tag3$$ The example by Ramanujan was, $$\begin{aligned} x &= \frac{\pi-\arcsin\big((\sqrt{5}-2)^3(4+\sqrt{15})^2\big)}{2}=1.094\dots\\ y &=\frac{\arcsin\big(\sqrt{5}-2\big)}{2}=0.119\dots\\ z &=\frac{\arcsin\big((\sqrt{5}-2)^3(4-\sqrt{15})^2\big)}{2}=0.0001\dots \end{aligned}$$ Ten years later, a 3-page proof was given in JIMS 15, p.114-117. I got an email asking if there was a shorter proof. Considering the problem, I observed the following. Given the quartic, $$a^3w^4+(1-3a^2)w^3+3a(1-a^2)w^2+a^2(3-a^2)w-a=0\tag4$$ with $a=\tan(\color{blue}y/4)$. Define, $$x=4\tan^{-1} u\\z=4\tan^{-1} v$$ where u,v are two appropriate roots of the quartic, then we get the same bizarre relation as Ramanujan, $$\big(\tfrac{1}{2}\sin x\cos z\big)^{1/4}+\big(\tfrac{1}{2}\cos x\sin z\big)^{1/4} =\big(\sin 2\color{blue}y)^{1/12}\tag5$$ Equivalently, those two roots u,v obey, $$\left(\frac{1}{2}\,\frac{4(u-u^3)}{(u^2+1)^2}\frac{v^4-6v^2+1}{(v^2+1)^2} \right)^{1/4}+\left(\frac{1}{2}\,\frac{4(v-v^3)}{(v^2+1)^2}\frac{u^4-6u^2+1}{(u^2+1)^2} \right)^{1/4}=\big(\sin 2\color{blue}y\big)^{1/12}\tag6$$ For example, let $y=1$, so $a=\tan(1/4)$, then u,v are the two real roots of (4). Question: Anyone knows a short proof for (3) and (6)?

A consequence of assuming the Descartes-Frenicle-Sorli Conjecture on odd perfect numbers

Let x be a positive integer. Denote the sum of divisors of x by $$\sigma(x) = \sum_{d \mid x}{d},$$ and the deficiency of x by $$D(x) = 2x - \sigma(x).$$ A number N is said to be perfect if $\sigma(N)=2N$. Euler proved that an odd perfect number, if one exists, must have the so-called Eulerian form $N = q^k n^2$, where q is the special prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. The Descartes-Frenicle-Sorli Conjecture on odd perfect numbers predicts that $k=1$. In the paper titled Conditions equivalent to the Descartes-Frenicle-Sorli Conjecture on odd perfect numbers - Part II, the following results are proved: If $N = q^k n^2$ is an odd perfect number given in Eulerian form, then $k=1$ if and only if $$N = \bigg(\frac{q(q+1)}{2}\bigg)\cdot{D(n^2)}.$$ If $N = q^k n^2$ is an odd perfect number given in Eulerian form, then $k=1$ if and only if $$N = \frac{n^2 \sigma(n^2)}{D(n^2)}.$$ Putting these two results together, we have that If $N = q^k n^2$ is an odd perfect number given in Eulerian form, then $k=1$ if and only if $$\bigg(\frac{q(q+1)}{2}\bigg)\cdot{D(n^2)} = N = \frac{n^2 \sigma(n^2)}{D(n^2)}.$$ This last equation implies that $k=1$ if and only if $$\bigg(D(n^2)\bigg)^2 = \frac{n^2}{(q+1)/2}\cdot\frac{\sigma(n^2)}{q}.$$ Here is my question: Does the equation $$\bigg(D(n^2)\bigg)^2 = \frac{n^2}{(q+1)/2}\cdot\frac{\sigma(n^2)}{q}$$ imply that $(q+1)/2$ and $\sigma(n^2)/q$ are both squares?

Sum of digits of a^b equals ab

The following conjecture is one I have made today with the aid of computer software. Conjecture: Let $s(\cdot)$ denote the sum of the digits of $\cdot$ in base 10. Then the only integer values $a,b>1$ that satisfy $$s(a^b)=ab$$ are $(2,2),(3,3),(3,6),(3,9)$ and $(3,27)$. Remarks: The number of digits of an integer n is $1+\lfloor\log_{10}n\rfloor$ where $\lfloor\cdot\rfloor$ denotes the floor function. This means that $s(a^b)<9+9\lfloor b\log_{10} a\rfloor$ as each digit takes a value of at most 9. From this plot it is evident that the equality will never hold for $a\ge 9$, after checking the first 21 values of b. Therefore it suffices to consider $2\le a\le 8$. I have excluded the case $b=1$ as it is trivial - it forces a to be a single-digit integer. In PARI/GP the code is given by mfun(b)={for(i=2,8,for(j=2,b,if(sumdigits(i^j,10)==i*j,print(i," ",j))));} and tests up to $b\le 10^6$ verify the above conjecture. Aside: The equation $s(ab)=a+b$ is much simpler to solve. From here, the upper bound $a\le 23$ is apparent and for these values of a, we can form the upper bound $b\le 22$ as there will be no solutions when the red line lies above the blue lines. This 23×22 grid can be computed through software and it is found that the only solutions are $$(a,b)=(2,2),(3,6),(6,3).$$ The similarity in the first two solutions with the conjectured solutions may only be coincidental. Advances on this will be appreciated.

Could prime numbers be defined like this?

While playing with prime numbers, I found the following definition. Let p be an integer. Then p is a prime number if and only if there is some integer $b \neq 1$ such that $$ \frac{b^p - 1}{b - 1} $$ is also a prime number. It is easy to show that the primality of p is a necessary condition for primality of $(b^p - 1)/(b - 1)$. I am however stuck to prove that, for given p, there is always at least one prime number of the form $(b^p - 1)/(b - 1)$. Is my definition correct, and if so, how to prove the second part? Any suggestion is welcome.

Is This a New Property I Have Found Pertaining to Mersenne Primes?

While playing with Mersenne numbers, I found the following property distinguishing Mersenne prime numbers from Mersenne composite numbers. A Mersenne number, $\text{M}p$, is a number of the form $2^p - 1$, where p is prime. Property For $p > 2$, Mersenne primes can be expressed as \begin{align*} \text{M}p = \frac{a^3 + b^3}{a + b}\text{,} \end{align*} where a and b are integers, $a \neq -b$, with exactly 12 different solutions. So far, also $\operatorname{gcd}(a,b)=1$ holds for Mersenne primes. Mersenne composites have either no integer solution or more than 12 solutions (24 so far). Also $\operatorname{gcd}(a,b)=1$ does not hold if the integer solutions exist so far. Examples \begin{align*} \text{M}5 &= \frac{6^3 + 5^3}{11} = 31 \\ \text{M}7 &= 7^3 - 6^3 = 127 \end{align*} The M11 has no integer solution for (a,b). The M37 has 24 solutions and also $\operatorname{gcd}(a,b)=1$ does not hold. Remarks Except the M2, twelve solutions exist for each Mersenne prime. If (a,b) is a solution, then also $(-a,-b)$, (b,a), and $(-b,-a)$ are. Since \begin{align*} \frac{a^3 + b^3}{a + b} = a^2 -ab + b^2 \text{,} \end{align*} each Mersenne prime has an ellipse intersecting integer grid associated with it. For example, $-a^2 + ab - b^2 + 127 = 0$ is the ellipse for M7. Results Solutions for the first few Mersenne numbers: $$\begin{matrix} p & \text{M}p & (a,b) \\ \hline 2 & 3 & (1,2) \\ 3 & 7 & (1,-2), (1,3), (2,3) \\ 5 & 31 & (1,-5), (1,6), (5,6) \\ 7 & 127 & (6,-7), (6,13), (7,13) \\ 11 & 2047 & \text{no solution} \\ 13 & 8191 & (1,-90), (1,91), (90,91) \\ 17 & 131071 & (6,-359), (6,365), (359,365) \\ 19 & 524287 & (83,-679), (83, 762), (679, 762) \\ 23 & 8388607 & \text{no solution} \\ 29 & 536870911 & \text{no solution} \\ 31 & 2147483647 & (4698, 43813), (4698,48511), (43813, 48511) \\ 37 & 137438953471 & \text{24 solutions} \\ 41 & 2199023255551 & \text{no solution} \\ 43 & 8796093022207 & \text{no solution} \\ ... & ... & ... \\ \end{matrix}$$ I have verified the conjecture using WolframAlpha for all p below 100. Question Can you confirm this result? Is this known? Any feedback is welcome.

Which other unsolved problems, have necessary restrictions on the prime gaps?

We all know of Unsolved problems, like Goldbach,Legendre, and Grimm's conjectures. Goldbach has the necessary condition of: There exists a prime between n and $2n-2$, which means prime gaps are limited to $n-3$ Legendre has a necessary condition of: Ratio's of primes never exceed $\left(\frac{n+2}{n} \right)^2$ Grimm's has a necessary condition (infinitely often) of: A prime gap never exceeds in length the number of primes less than the prime proceeding the gap. My Question is: What other unsolved problems, have necessary conditions on the size of prime gaps?

Finding a counterexample to a Prime Factorization Conjecture

Let $\mathbb{Z}_{\geq 2}$ be the set of natural numbers starting at 2: $$\mathbb{Z}_{\geq 2}= \{2, 3, 4, 5,\ldots\}.$$ An natural number's prime factorization is odd if the total number of primes in its factorization is odd. It is even if the total number of primes in its factorization is even. Let $N(k) = \{j \mid j\in \mathbb{Z}_{\geq 2}, j\leq k\text{, the prime factorization for j is odd}\}$. Let $n(k) = |N(k)|$ Let $A(k) = \{j \mid j\in \mathbb{Z}_{\geq 2}, j\leq k\text{, the prime factorization for j is even}\}$. Let $a(k) = |A(k)|$ Conjecture: $n(k) \geq a(k)$ for all prime numbers k in $\mathbb{Z}_{\geq 2}$.

Equivalence of Frankl's Conjecture

Frankl’s conjecture is one of the most famous problems in combinatorics. Frankl's conjecture claims: For every finite non-empty set A and for every Frankl's family F on A exists $a\in A$ such that $$|\{X\in F | a\in X \}|\geqslant \frac{|F|}{2}.$$ How can be proved that Frankl's conjecture is equivalent to next statement: For every finite lattice L exists $a \in\mathcal{M}(L),$ such that $|a\downarrow|\leqslant \frac{|L|}{2},$ where $\mathcal{M}(L)$ is the set of all strictly $\wedge$-irreducible elements of L and $a ↓ = \{b ∈ L | b ≤ a\}?$

Almost a prime number recurrence relation

For the number of partitions of n into prime parts $a(n)$ it holds $$a(n)=\frac{1}{n}\sum_{k=1}^n q(k)a(n-k)\tag 1$$ where $q(n)$ the sum of all different prime factors of n. Due to https://oeis.org/A000607. I have found that $$a(p_n)\approx a(p_{n-2})+a(p_{n-1})\tag 2$$ and conjecture the asymptotic relation. $$\log a(p_n)\sim

\log \big(a(p_{n-2})+a(p_{n-1})\big)\tag 3$$ On x-axis the prime numbers p_n are plotted. The blue lines correspond to $a(p_n)$ and the red lines correspond to $a(p_{n-2})+a(p_{n-1})$. On the oeis site above there is also a formula $$a(n)\sim e^{2\pi\sqrt{n/\log n}\,/\sqrt{3}}\tag 4$$ but I don't know if this really helps? Can this (reformulated) conjecture be proved?

Group (mathematics) Conjecture

Given $(G,•)$ as a Group with finite set G, operator •. Define: subset $S \subset G$ is called the core of the Group if and only if $$ \{ x•y ~|~ x \in S, y \in S \} = G \setminus S$$ Conjecture 1: if G has at least two elements, core exists. Conjecture 2: if core exists, any two cores have the same cardinality. Conjecture 2.1: given prime $p \ge 3$, for $G = \{1,2,\ldots,p-1\}$ and operator • is 'multiplication modulo p', then any core $S \subset G$ has cardinality $(p-1)/2$. Example: $p = 7$, $S = \{3,5,6\}$ $1 \equiv 3*5 \equiv 6*6\pmod{7}$ $2 \equiv 3*3 \equiv 5*6\pmod{7}$ $4 \equiv 3*6 \equiv 5*5 \pmod{7}$ Question: anyone can find any (related) reference of the definition of core?

An explicit "formula" for the prime counting function?

It is known that $\log(p_1),\cdots,\log(p_n)$ are linearly independet over $\mathbb{Q}$, where p_i denotes the i-th prime. For a number $1 \le k \le n$ let $Log(k)$ denote the vector with respect to this basis for the numbers $1,\cdots,n$. For a subset A of $1,\cdots,n$ let $rank(A)$ denote the rank of the matrix build by numbers k in A of vectors $Log(k)$. Through experimentation I found the following explicit "formula" for prime-pi function: $$ \Pi(n)= (-1)^{n+1} \sum rank(A) \cdot (-1)^{|A|}$$ where A runs through the subsets of $1\cdots n$ of size $< n$. But I have no proof for this. The formula above has some similarity with the inclusion-exclusion principle: $$\left| \bigcup_{i=1}^n A_i\right| = \sum_{\emptyset\neq J\subseteq\{1,\ldots,n\}}(-1)^{|J|-1} \left |\bigcap_{j\in J} A_j\right|$$ But how does one define the sets A_i? The formula has also similarity with Euler characteristic. For a set of (possibly repeating) vectors, define: $$\chi(v_1,\cdots,v_n) = \sum_{A} rank(A) \cdot (-1)^{|A|}$$ where A runs through the subsets (with repetion) of $v_1,\cdots,v_n$. It is not difficult to show, that if those vectors are linearly independent then $$\chi=0$$ My conjecture is that if $\chi(v_1,\cdots,v_n)=0$ then $$\chi(v_1,\cdots,v_n,w)=0$$ for any vector w. This would prove the prime-counting formula. If you can think of a proof, that would be great. Related-but-not duplicate question: https://mathoverflow.net/questions/325880/is-this-line-of-thought-using-linear-algebra-to-get-number-theoretic-results-a Here is some sage code to play around with: MAXN=100 def Log(a,N=MAXN): return vector([valuation(a,p) for p in primes(N)]) def findsubsets(S,m): return Set(S).subsets(m) def getMatrixA(someSubset,N=MAXN): return matrix([Log(xx,N=N) for xx in someSubset]) def eulerCharPrimePi(n,N=MAXN): return (-1)^(n+1)*sum([getMatrixA(x).rank()*(-1)^k if k < n else 0 for k in range(0,n+1) for x in findsubsets(range(1,n+1),k)])

Conjecture about primes and the greatest common divisor

Conjecture: Given $m,n\in\mathbb N^+$, one odd and one even, there are two primes p,q such that $|mp-nq|=\gcd(m,n)$. I hope MSE can determine its validity. From time to time, when testing my growing math packages BigZ and Forthmath, I recognize some patterns which I can't prove or disprove (or even have the ambition to). I post them here with the hope that it will not annoy too much. I hope you can bear with it.

Symmetry conditions for symmetric random vectors

While formulating the properties for a certain statistical model I'm dealing with, I came up with the following question (with credit going to MikeEarnest in comments for the proper formulation). A random variable X is symmetric (about zero) if X and $-X$ are identically distributed. This in particular applies to the case of a random vector. The question is then: Suppose $X=(X_1,X_2,\ldots, X_n)$ is a random vector such that $(X_{i(1)},X_{i(2)},\ldots,X_{i(m)})$ is symmetric for any $\{i(1),i(2),\ldots,i(m)\}\subseteq \{1,2,\ldots,n\}$. Does it follow that X is symmetric? This statement is probably too generic, given the lack of assumptions on X beyond symmetry. If I specialize to the case where each X_k can only take values ± 1, then my understanding is that the above is true when $m=1$ regardless of n. (This would imply that it is true for arbitrary m, since the subsets of $\{1,2,\cdots, n\}$ of size at most m includes the singletons.) However, if I move to X_k taking values in $\{1,0,-1\}$ then the case of $m=1$ fails (see the comments for a counter-example due to MikeEarnest) and I don't know what can be said about $m>1$. This gives me the following (admittedly imprecise) question: What assumptions on the maximum size m and the distribution of the random variables $\{X_k\}_{k=1}^n$ must be made in order for the above statement to be valid? I would also be interested in additional

counter-examples.

On a conjecture that two intersections are at $\big(\pm\frac{S}m, S\big)$ (about linear equations)

Suppose we have two linear equations, $y=mx$ and $y=-mx$, inserted on the same plane for $m>0$. These equations are going to have an intersection at $(0,0)$. Now, let $$\begin{align}S&=1+\sum_{i=2}^{m-1}\left(i-\frac12\right)\\ &\stackrel{\small\text{or}}{=}1+\left\{\bigg(2-\frac12\bigg)+\bigg(3-\frac12\bigg)+\cdots+\bigg(m-1-\frac12\bigg)\right\}.\end{align}$$ If we insert the equation, $y={m^2+1 \over 2}$, on the selfsame plane, then this horizontal line will pass through both the aforementioned linear equations, thus forming two more intersections. Conjecture: The two intersections are at $\big(\pm\frac{S}m, S \big)$, such that the positive x coordinate is on the RHS of the y axis, and the negative x coordinate is on the LHS of the y axis. This is my own conjecture actually... and I can't seem to prove it. The following is my attempt, in which I did make some progress... but it is not a proof (...yet). Attempt: $$\begin{align}S&=1+\left\{\bigg(2-\frac12\bigg)+\bigg(3-\frac12\bigg)+\cdots+\bigg(m-1-\frac12\bigg)\right\}\tag{given} \\ \\ 2\cdot S&=2+(4-1)+(6-1)+\cdots+(2m-2-1)\tag{$\times 2$} \\ &=\require{cancel}{\cancel2}+(4-1)+(6-1)+\cdots+(2m\cancel{-2}-1)\tag{$2-2=0$} \\ &=(4-1)+(6-1)+\cdots+(2m-1)\tag{simplifying} \\ &=\sum_{i=2}^m(2i-1).\tag{$\ast$}\end{align}$$ Here, we can use the following lemma to enable us to write Eq. $(\ast)$ in closed form: $$\sum_{j=1}^n(2j-1)=n^2.$$ The proof of this lemma can be found in Intermediate Mathematics: Proof by Induction in Page 8, Section 2, Example 3. By letting $n=m$ and $j=i$, we can rewrite this lemma and obtain the following: $$\begin{align}\sum_{i=1}^m(2i-1)&=(2\times 1-1)+\sum_{i=2}^m(2i-1) \\ \Leftrightarrow m^2&= 1+\sum_{i=2}^m(2i-1) \\ \Leftrightarrow \sum_{i=2}^m(2i-1)&= m^2-1 \\ \Leftrightarrow 2S&=m^2-1\end{align}$$ $$\boxed{\therefore S=\frac{m^2-1}{2}}\tag*{$\quad\quad\quad

infinity}$$ Therefore, evaluating an upper bound should be a simple as solving the equation $$L_n=L_{n+1}\stackrel{\text{in the example}}{\implies}L_n=\frac{L_n+1}{L_n+2}\implies L_n=\frac{-1+\sqrt5}{2}$$ Another example would be, for instance, the sequence defined recursively as follows $$M_{n+1}=\frac{M_n}{3}+\frac{1}{M_n}\qquad \text{where}\quad M_0=4$$ which converges to $\sqrt{\frac{3}{2}}$. This leads to Conjecture Suppose there's a recursive sequence $\{L_n\}^\infty_{n=0}$ that converges to k, where $L_{n+1}-L_n\to 0$ as n approaches infinity. Then, k is one of the solutions to the equation $$L_n=L_{n+1}$$

Conjecture on the growth of $q_1 = 1, q_{n+1}=q_n + f(q_n) $

This is a generalization of my answer to Calculate the limit of the following recurrent series in the form suggested by Will Jagy. $q_1 = 1, q_{n+1}=q_n + f(q_n) $ where $f(x) > 0$ and $f'(x) < 0$. I show that q_n is unbounded and derive a conjecture for the growth of q_n as a function of $f(x)$. To make my question explicit (since some people seem to want that): Is my conjecture on the growth of q_n true? My conjecture for $f(x) = \dfrac{a}{x^b} $ is $q_n \approx (a(b+1)n)^{1/(b+1)} $ and for $f(x) = \dfrac{a}{b^x} $ is $q_n \approx \dfrac{\ln(a\ln(b)n)}{\ln(b)}$. First, a proof that q_n is unbounded. $q_n > 1$ for $n > 1$ and q_n is increasing. If q_n is bounded, there is an L such that $q_n \le L$ for all n so that, since $f'(x) < 0$, $f(q_n) \ge f(L)$. Writing $q_{n+1}=q_n + f(q_n) $ as $q_{n+1}-q_n = f(q_n) $ and summing $\begin{array}\\ q_{n+1}-q_1 &=\sum_{k=1}^n (q_{k+1}-q_k)\\ &=\sum_{k=1}^n f(q_k)\\ &\ge\sum_{k=1}^n f(L)\\ &= nf(L)\\ \end{array} $ which is unbounded, a contradiction. Now to get an estimate for q_n in terms of $f(x)$. Suppose $q_n = g(n)$ where g is a reasonably smooth function (i.e., has at least a first derivative). Then $\begin{array}\\ q_{n+1}-q_n &=g(n+1)-g(n)\\ &=g'(n+c) \qquad\text{where } 0 \le c \le 1\\ &\approx g'(n) \qquad\text{this is the big assumption}\\ \end{array} $ Therefore $g'(n) \approx f(q_n) =f(g(n)) $. This is the functional equation that g has to satisfy. For example, if $f(x) = \frac{2}{x}$ as in the original problem, the equation is $g'(n) =\frac{2}{g(n)} $ so $2 = g(n)g'(n) =\frac12(g^2(n))' $. Integrating, $4n+c =g^2(n)$ so $g(n) = 2\sqrt{n+c_1} $. This agrees with my conjecture in my answer to the original question. More generally, if $f(x) = ax^{-b}$ where $a, b > 0$, the equation is $g'(n) =a(g(n))^{-b} $ or $a = g'g^b =\frac1{b+1}(g^{b+1})' $. Integrating, $a(b+1)n+c =g^{b+1}(n) $ so $g(n) =(a(b+1)n+c)^{1/(b+1)} $. As a check, simplifying with $c=0$, $g(n) = (a(b+1)n)^{1/(b+1)}$ so $\begin{array}\\ g(n+1)-g(n) &=(a(b+1)(n+1)^{1/(b+1)}-(a(b+1)n)^{1/(b+1)}\\ &=(a(b+1)n)^{1/(b+1)}((1+1/n)^{1/(b+1)}-1)\\ &=(a(b+1)n)^{1/(b+1)}(\frac1{(b+1)n}+O(\frac1{n^2}))\\ &=a^{1/(b+1)}((b+1)n)^{1/(b+1)-1}+O(\frac1{n^{2-1/(b+1)}})\\ &=a^{1/(b+1)}((b+1)n)^{-b/(b+1)}+O(\frac1{n^{2-1/(b+1)}})\\ &=\dfrac{a^{1/(b+1)}}{((b+1)n)^{b/(b+1)}}+O(\frac1{n^{1+b/(b+1)}})\\ \text{and}\\ f(g(n)) &=\dfrac{a}{g^b(n)}\\ &=\dfrac{a}{((a(b+1)n)^{1/(b+1)})^b}\\ &=\dfrac{a}{(a(b+1)n)^{b/(b+1)}}\\ &=\dfrac{a^{1/(b+1)}}{((b+1)n)^{b/(b+1)}}\\ \end{array} $ Another class of functions, suggested by Will Jagy, is $f(x) = \frac{a}{b^x}$ where $a > 0, b > 1$, the equation is $g'(n) =\frac{a}{b^{g(n)}} $ or $a = g'b^g = g'e^{g\ln(b)} =\frac1{\ln(b)}(e^{g\ln(b)})' =\frac1{\ln(b)}(b^g)' $. Integrating, $a\ln(b)n+c =b^g $ so $g(n)\ln(b) =\ln(a\ln(b)n+c) $ or $g(n) =\dfrac{\ln(a\ln(b)n+c)}{\ln(b)} $. If $a=1, b = e$ as in Will Jagy's example, $g(n) =\ln(n+c) $. To check, if $c = 0$, $g(n) = \dfrac{\ln(a\ln(b)n)}{\ln(b)}$ so $\begin{array}\\ g(n+1)-g(n) &=\dfrac{\ln(a\ln(b)(n+1))}{\ln(b)}-\dfrac{\ln(a\ln(b)n)}{\ln(b)}\\ &=\dfrac1{\ln(b)}(\ln(a\ln(b)(n+1))-\ln(a\ln(b)n))\\ &=\dfrac1{\ln(b)}\ln(1+1/n))\\ &=\dfrac1{n\ln(b)}+O(\frac1{n^2})\\ \text{and}\\ f(g(n)) &=\dfrac{a}{b^{g(n)}}\\ &=\dfrac{a}{b^{\frac{\ln(a\ln(b)n)}{\ln(b)}}}\\ &=\dfrac{a}{a\ln(b)n}\\ &=\dfrac1{\ln(b)n}\\ \end{array} $

How does one subtract from concatenation in order to prove that $4\times 5 + 67 = 45 + 6\times 7$?

I noticed that if we get the numbers 4, 5, 6 and 7, they have an interesting property! $$4 \times 5 + 67 = 45 + 6 \times 7\tag*{= 87.}$$ I then conjectured that these were the only four consecutive positive integers with this property. Hmm... Let the four integers be n, $n+1$, $n+2$ and $n+3$. Then we have $$\begin{align} &n(n+1) + (n+2)\| (n+3) \\ =\;&n\| (n+1) + (n+2)(n+3).\tag{$\|\;\small{ \rm stands\;for}\;concatenation$}\end{align}$$ Or $$\begin{align} (n+2)\|(n+3)-n\|(n+1)&=(n+2)(n+3)-n(n+1) \\ &=n^2 + 5n + 6 - n^2 - n \\ &= 4n+ 6 \\ &= 2(2n+3).\end{align}$$ Now this is when I noticed that if $n=4$ then $2(2n+3)=22$. I may be able to reach 22 like so: $$\begin{align}(n+2)\|(n+3)-n\|(n+1)&=(n+2-n)\|(n+3-n-1)\\ &=2\|2 \\ &= 22\end{align}$$ If that is true, then this happens: $$\begin{align}22 &= 2(2n+3)\\ \Leftrightarrow \; 11 &= 2n+3 \\ \Leftrightarrow \; 8 &= 2n \\ \\ \therefore \; n &= 4.\end{align}$$ This is my desired result, thus proving the conjecture. But is the equation in the second sandbox true? How does one subtract from concatenation? This, in particular, is new to me; I would mostly appreciate a full, explanatory answer. Thank you in advance.

For every b in the power a^{b}, does there exist an a such that the digit sum of this power is equal to a?

$1^0 = 1\to 1 =1$ $x^1=x\to x=x\;\forall x$. $9^2 = 81\to 8+1=9$ $8^3=512\to 5+1+2=8$. $7^4=2401\to 2+4+0+1=7$ $46^5 = 205962976\to 2+0+5+9+6+2+9+7+6=46$ $64^6 = 68719476736\to 6+8+7+1+9+4+7+6+7+3+6 = 64$ $68^7= 6722988818432\to 6+7+2+2+9+8+8+8+1+8+4+3+2 = 68$ $54^8 = 72301961339136\to 7+2+3+0+1+9+6+1+3+3+9+1+3+6=54$ $71^9 = 45848500718449031$ $\downarrow$ $4+5+8+4+8+5+0+0+7+1+8+4+4+9+0+3+1 =

71$ Conjecture: Given a positive integer b, there exists a positive integer a such that the digit sum of a^b is equal to a. Can this be proven? I don't know how to prove it; it was about 3:45am in the morning and I couldn't go to sleep, so I just went on my calculator and messed around because I was bored. That's when I noticed this cool property and decided to share it here. It is now 4:35am so... I gotta go to bed. I'll see you in some hours and hopefully gather the time to work on this. Sorry about that! Oh, incidentally, I also noticed that the digit sum of 29^5 is 23 and the digit sum of 23^5 is 29, so... there are cycles here. Same for 31 and 34. Also, the digit sum of 13^2 is 16 and the digit sum of 16^2 is 13. These cycles seem to only have two numbers involved, but I think regarding the seventh power, there is more than two involved (start with 72^7 I think), however there is also a cycle between two numbers of seventh powers (between 44 and 62). Does this help? I don't know. I have to go to bed. Good night! Thank you in advance.

Minimal order of a counterexample to Wall’s conjecture

There used to be once a rather well known and interesting conjecture, that was formulated by Gordon E. Wall: The number of maximal subgroups of a finite group G does not exceed $|G|$ That conjecture appeared to be false. However, the only information about it, that I was able to find, was this MO answer. It contains the statement, that the conjecture was disproven, and a link to the research in which the counterexamples were found. That link, however, seems to be already dead by the time I got there. So, my question is, what is the minimal possible order of a counterexample to Wall’s conjecture? Or, in case, if that is unknown yet, the minimal order of a known counterexample to Wall’s conjecture? I need this kind of information for my collection of disproven conjectures in combinatorics

Are there infinitely many solutions such that the digit sum of a prime power is a smaller power of the same prime?

While discussing prime powers and divisors, I came up with the following problem. Examples $\to$ prime $p=3$ digit sum (in base ten) of $p^3=27$ is $p^2=9$, a power of p,. $\to$ prime $p=7$ digit sum of $p^4=2401$ is $p^1=7$, a power of p. We can get even crazier: $\to$ prime $p=5$ digit sum of p^{208} is equal to $p^4=625$. and so on. The PARI/GP code used to generate the examples is below: sfun(p,k,n)={for(q=2,n,if(sumdigits(p^q,10)==p^k,print(q)))}. Questions Main question: Denote the digit sum (in base ten) of an integer m as $s(m)$. Are there infinitely many solutions such that $$s(p^n)=p^k$$ where p is a prime, and k,n are positive integers? When $p=3$, it has the nice property that $s(3^n)$ is always divisible by 3, so the first few solutions are not very hard to find. For example, when $k=3$, we obtain $n=9,10,11,13,16,17,21$. Some experimentation with the code reveals that the solutions get sparser as p increases, as expected. But the solutions themselves are very unexpected, such as $$s(5^{4938})=5^6,\quad s(89^{898})=89^2.$$ Thus I believe in the finitude of the solutions, but I think evaluating them will be out of the question. To disprove my claim, it suffices to show that for every p there is a solution, since we know that the number of primes is infinite.

Are 2, 3 the only prime numbers that don't have the digit 1 and are palindromes whose squares are also palindromes?

While thinking about prime numbers, I noticed that: (1) Very few prime numbers have squares that are palindromes. Ex: 2, 3, 11, 101, 307 (2) Even rarer are prime numbers that are palindromes whose square are palindromes. Ex. 2, 3, 11 This inspired me to ask the following questions: (1) Are $2, 3$ the only prime numbers that don't have the digit 1 and are palindromes whose squares are also palindromes? (2) If not, then are there a finite number of these types of these prime numbers.

Pairs of palindromic primes without 1 and have a palindromic product

While discussing about prime numbers with other users, I noticed that: (1) There are very few pairs of palindromic prime numbers that do not contain the digit 1 and that have products which are palindromes. Ex : $[2, 3], [2, 30203], [2, 30403]$ (2) For the large range that was tested on PARI/GP, I noticed that all the palindromic primes that yielded palindromic products were composed only of the digits $0, 2, 3, 4$ (3) The palindromic primes of these pairs are equal to 2 or always exist in the range of 3×10^k to 4×10^k where $k \in \Bbb{+Z}, 0$ User Peter helped me get the following results for $a, b \lt 10^7$ on PARI/GP: [2, 3] [2, 30203] [2, 30403] [2, 32323] [2, 32423] [2, 3002003] [2, 3222223] [2, 3223223] [2, 3233323] [2, 3304033] [2, 3343433] [2, 3400043] [2, 3424243] [2, 3443443] [2, 3444443] [3, 30203] [3, 32323] [3, 3002003] [3, 3222223] [3, 3223223] [3, 3233323] [30203, 3002003] Questions: (1) Are there a finite number of pairs of a, b, where a, b are palindromic primes that do not contain the digit 1 and ab is a palindrome? (2) Are all the palindromic primes that yielded palindromic products composed only of the digits $0, 2, 3, 4$? (3) Are all the palindromic primes of these pairs equal to 2 or always exist in the range of 3×10^k to 4×10^k where $k \in \Bbb{+Z}, 0$?

New results on Identical Binomial Coefficient?

Are there any nontrivial identical binomial coefficients found other than: $$ {16 \choose 2}={10 \choose 3}=120 \\ {21 \choose 2}={10 \choose 4}=210 \\ {56 \choose 2}={22 \choose 3}=1540 \\ {120 \choose 2}={36 \choose 3}=7140 \\ {153 \choose 2}={19 \choose 5}=11628 \\ {221 \choose 2}={17 \choose 8}=24310 \\ {78 \choose 2}={15 \choose 5}={14 \choose 6}=3003$$ and the infinite family (where F_n is the nth fibonacci number): $$ {F_{2i+2}F_{2i+3} \choose F_{2i}F_{2i+3}}={F_{2i+2}F_{2i+3}-1 \choose F_{2i}F_{2i+3}+1}$$ By non-trivial I mean, of the shape ${n \choose k}$ where $2\leq k \leq \frac{1}{2}n $. This was conjectured to be the complete list in a paper from 1996: https://pdfs.semanticscholar.org/69fe/a6ef6f5ac5818538a86e98ddd9236a3310f7.pdf Are there any new results?

Proof that the error between $W(\lambda(\sqrt{n}))$ and the fraction of composite integers in $\mathbb{O}_n$ declines as n increases.

Please provide assistance for the proof that the error between the function $W(\lambda(\sqrt{n}))$ and the fraction of composite integers in $\mathbb{O}_n$ declines as n increases. Let $\mathbb{O}_n$ represent the set of odd integers less than or equal to n excluding 1. $\mathbb{O}_n$ = {3,5,7,9,11,13,15,17,19,...n} Let the function $l(x)$ equal the largest prime number less than x. For example: $l(10) = 7, l(20) = 19$ and $l(23) = 19$ Let the function $\lambda(x)$ equal the largest prime number less than or equal to x. For example: $\lambda(10) = 7, \lambda(20) = 19$ and $\lambda(23) = 23$ The function $W(\lambda(\sqrt{n}))$ was derived to represent the fraction of composite integers in the set $\mathbb{O}_n$ for large values of n. \begin{eqnarray*} W(\lambda(\sqrt{n})) = \sum_{\substack{p=3\\p\ \text{prime}}}^{\lambda(\sqrt{n})}\left((\frac{1}{p})\prod_{\substack{q=3\\q\ \text{prime}}}^{l(p)}\frac{(q-1)}{q}\right) \end{eqnarray*} or $W(\lambda(\sqrt{n}))= \frac{1}{3} + (\frac{1}{5})(\frac{2}{3}) + (\frac{1}{7})(\frac{2}{3})(\frac{4}{5}) + ... + (\frac{1}{ \lambda(\sqrt{n}))})(\frac{2}{3})(\frac{4}{5})(\frac{6}{7})(\frac{10}{11})...(\frac{(l(\lambda(\sqrt{n})) - 1)}{l(\lambda(\sqrt{n}))})$.\ I have proven that the maximum error between $W(\lambda(\sqrt{n}))$ and the actual fraction of composite integers in the set $\mathbb{O}_n$ declines as n increases in sections 6 and 7 in this paper http://vixra.org/pdf/1901.0436v5.pdf. Is this proof sufficient? If not, what needs to be done? Please only post helpful information.

Can the product of n positive integers, where $n \gt 5$ in A.P. be a palindrome?

Reading the question can the product of four positive integers in A.P. be a square?, also made me question whether the product of n positive integers, where $n \gt 5$ in arithmetic progression be a palindrome? Me and user Peter tried to find solutions for various n in PARI/GP, and found that there were no solutions for a large range of numbers we tested when $n \gt 5$. This led to the following questions: (1) Can the product of n positive integers, where $n \gt 5$ in A.P. be a palindrome? (2) If yes then for what value of n is there no solution?

Is the set of elementary functions which do not have elementary integrals bigger than set of elementary functions which have elementary integrals?

It increasingly seems to me that the functions that have elementary integrals are quite rare in comparison to the ones that don't have them. Even raising an elementary function to a different power may result in it not having an elementary integral . Ex. $\sqrt{\arctan (x)}$ Also many seemingly simple functions do not have elementary integrals. Ex. $\frac {\sin (x)}{x}$ or $ \sin \left(\frac{1}{x} \right) $ So my question is that can we write a formal proof to prove/disprove that the set of elementary functions which do not have elementary integrals is bigger than set of elementary functions which have elementary integrals?

A conjectured identity for the fractional iterates of $\sqrt{x}+2$

Deeply impressed by the Fractional iterates of $x²-2$, a problem by Ramanujan post one month ago, I decided to investigate a little by myself on the topic and discovered that using Carleman matrices would be of great help for that purpose. After various numerical computations, and helped by several algorithms for recognizing patterns and guessing formulas, I finally came accross a differential equation detected in a Carleman matrix (by the guessHolo function in the FriCAS computer algebra system) which I could easily solve in order to write down the following identity: $$ F^{[n]}(x) = 2 + 2\cosh\left(2^{1-n}\,\textrm{arcsinh}\!\left(\frac {\sqrt{x-4}}{2}\right)\right) $$ with $F(x) = \sqrt{x} + 2$. Plotting this function for various values of n between 1 and 2 together with the functions F and $F^{[2]}$ shows how smoothly the interpolation works. Now, I don't know if this is something trivial or not and would be very happy to learn about it. Is such a result already known?

Asymptotic frequency of $[0,\,1,\,1]$ in the Thue-Morse sequence

Let t_n be the Thue-Morse sequence: $$[\color{blue}{0,\,1,\,1,\,0,}\,\color{red}{1,\,0,\,0,\,1,}\,\color{blue}{1,\,0,\,0,\,1,}\,\color{red}{0,\,1,\,1,\,0,}\,...].\tag1$$ See this question for a definition and formula for t_n. Let's split the sequence into non-overlapping runs of length 3: $$[\underline{[\color{blue}{0,\,1,\,1}]},\,[\color{blue}{0,}\,\color{red}{1,\,0}],\,[\color{red}{0,\,1,}\,\color{blue}1],\,[\color{blue}{0,\,0,\,1}],\,\underline{[\color{red}{0,\,1,\,1}]},\,...].\tag2$$ There are 6 different sorts or runs in this sequence: all possible combinations of 0 and 1 except $[0,\,0,\,0]$ and $[1,\,1,\,1]$ - the Thue-Morse sequence is cube-free. What is the asymptotic frequency of the $\underline{[0,\,1,\,1]}$ run? Empirically, it seems to be around $\style{color:#bbbbbb;text-decoration:line-through}{1/5}\,1/6$, but the convergence is quite slow and erratic.

Integrals of the Bessel function $J_0(x)$ over the intervals between its zeros

Let $J_0(x)$ be the Bessel function of the first kind. It has an infinite number of zeros on the positive real semi-axis. Let's denote them as $j_{0,n}$: $$j_{0,1}=2.40482...,\quad j_{0,2}=5.52007...,\quad j_{0,3}=8.65372...,\quad\small...\tag1$$ We are interested in absolute values of the integrals of $J_0(x)$ over the intervals between its consecutive zeros: $$\sigma_n=(-1)^n\int_{j_{0,n}}^{j_{0,n+1}}\!\!J_0(x)\,dx.\tag2$$ Their values are: $$\sigma_1=0.80145...,\quad\sigma_2=0.59932...,\quad\sigma_3=0.49904...,\quad\small...\tag3$$ We are interested in the asymptotic behavior of this sequence. Empirically, it seems that $$\sigma_n\,\stackrel{\color{#a0a0a0}?}\sim\,\frac{2\sqrt2}{\pi\sqrt n}\left(1-\frac1{8n}+O\!\left(\frac1{n^2}\right)\right)\!.\tag4$$ Can we prove this? Can we find next coefficients in this expansion?

A question on discrete Fourier transform of some function

Let $\sigma(n) = \sum_{d|n} d$ and $\tau(n) = $ number of divisors of n. For each $k, 0 \le k \le n-1$ we can look at the discrete Fourier transform of the numbers $\sigma(\gcd(n,k))$ given by: $$\hat{\sigma}(k) = \sum_{l=0}^{n-1} \sigma(\gcd(n,l))\exp\left(\frac{-2 \pi i k l }{n}\right)$$ I implemented this in SAGEMATH, and it occured me that : Conjecture: $$\hat{\sigma}(k) = n \tau(\gcd(n,k))$$ Is there any way to prove this? Here is some sage-code which implements this: def tau(n): return len(divisors(n)) def FTS(n,k): # Fourier Tranformierte von sigma(gcd(n,k)) return sum([sigma(gcd(n,l))*exp(-2*pi*I/n*k*l) for l in range(n)]) N = 8 for k in range(N): print k,abs(FTS(N,k).N()),N*tau(gcd(N,k)) which gives: 0 32.0000000000000 32 1 8.00000000000000 8 2 16.0000000000000 16 3 8.00000000000000 8 4 24.0000000000000 24 5 8.00000000000000 8 6 16.0000000000000 16 7 8.00000000000000 8 Edit: From the conjecture above it follows, that, by setting $k=0$: $$\tau(n) = \frac{1}{n}\sum_{l=0}^{n-1} \sigma(\gcd(n,l))$$ for which I have a proof. By taking the inverse Fourier transform, and setting again $k=0$ we get: $$\sigma(n) = \sum_{l=0}^{n-1} \tau(\gcd(n,l))$$

Is it still unknown whetever any $\mathscr{D}$-class D being a semigroup is bisimple?

Introduction: It is stated in my book from year 1961 that it is unknown whatever a subsemigroup D of semigroup S, which is also a $\mathscr{D}$-class of S is always bisimple, but it is known for $\mathscr{D}$-classes which are regular. Is it still unknown to this day? If it have been solved, can you provide sources? Definitions: Definition 1: We say that the elements x and y belonging to the semigroup S are in the same $\mathscr{L}$-class ($\mathscr{R}$-class) if and only if they generate the same left (right) principal ideal, that is, if $S^1x = S^1y$ ($xS^1 = yS^1$) holds. Definition 2: We say that elements x and y of S belong to the same $\mathscr{D}$-class if and only if $(x, y)\in\mathscr{L}\lor \mathscr{R}$ (the joint of relations $\mathscr{L}$ and $\mathscr{R}$). As an alternative definition, it can be shown that relations $\mathscr{L}$ and $\mathscr{R}$ commute, and hence $\mathscr{D} = \mathscr{L}\circ\mathscr{R} = \mathscr{R}\circ\mathscr{L} $, that is x and y belong to the same $\mathscr{D}$-class if and only if there exists z such that $x\mathscr{L}z\mathscr{R}y$. Definition 3: We say that the semigroup S is bisimple, if and only if there is a single $\mathscr{D}$-class in S.

Circular Happy Palindromic Primes

(1) A circular prime is a prime number with the property that the number generated at each intermediate step when cyclically permuting its (base 10) digits will be prime. For example, 1193 is a circular prime, since 1931, 9311 and 3119 all are also prime. (2) A happy number is defined by the following process: Starting with any positive integer, replace the number by the sum of the squares of its digits in base-ten, and repeat the process until the number either equals 1 (where it will stay), or it loops endlessly in a cycle that does not include 1. Those numbers for which this process ends in 1 are happy numbers. For example, 19 is happy, as the associated sequence is $1^2 + 9^2 = 82,$ $8^2 + 2^2 = 68,$ $6^2 + 8^2 = 100,$ $1^2 + 0^2 + 0^2 = 1.$ (3) A palindromic prime is a prime that remains the same when its digits are reversed. For example, 11 A Circular happy palindromic prime is a prime number that has all three of the above properties. According to my testing in PARI/GP and my own results, I have found the following circular happy palindromic primes: $7, 1111111111111111111$ (19 digits)$, 1111111111111111111111$ (23 digits) (Haven't

tested complete range of 10^{24} in PARI/GP) Note that 19 and 23 are happy primes themselves which explains why $111111111111111111, 11111111111111111111111$ are also happy primes. Questions: (1) Are $7, 111111111111111111, 11111111111111111111111$ the only circular happy palindromic primes? (2) Are $1111111111111111111, 11111111111111111111111$ the only happy primes of the form 11111.... ? (3) If not then are there a finite number of circular happy palindromic primes? Can we prove/disprove this?

Create & Prove Conjecture - Discrete Math (Proofs)

I am stuck on the following problem: Imagine that a building has been overrun with snakes and rats. To help curb the problem, the building manager decides to offer employees brownie points for capturing and relocating them. They offer 13 points for each snake and 6 points for each rat captured and removed. Make a conjecture about what totals for points are possible. For example, an employee could not earn 7 points in this scenario. Prove that your conjecture is true. What "conjecture" am I supposed to be making? I assume I am trying to find a fact/pattern; something like "points can only be obtained in multiples of 6", but I am lost. I only managed to find that the two provided numbers, 6 and 13, are relatively prime. Of course, I also need to figure out how to prove such conjecture, I just can't do that until after I make it. Edit: Okay, I totally misread the example conjecture. So my conjecture will be "an employee could not earn 14 points in this scenario". I write the following proof: Proof: The two values of obtainable points are 6 and 13. The first 5 possible combinations of sums of 6 and 13 are, in order, as follows: { (0), (6), (6+6), (13), (13+6), (6+6+6) } = { 0, 6, 12, 13, 18 } There are no possible combinations of sums of 6 and 13 that equate to 14. Therefore, it is impossible for an employee to earn 14 points in this scenario.

Is 29 the only prime of the form p^p+2?

I searched for primes of the form p^p+2, where p is prime for a range of $p \le 10^5$ on PARI/GP and found that 29 is the only prime of this form in this range. Questions: (1) Is 29 the only prime of the form p^p+2, where p is prime? (2) If not, then are there a finite number of primes of the form p^p+2? Can you prove/disprove this? Edit: Since p^p grows really fast and primes get rarer and are spread farther out for large numbers, I conjecture that 29 is the only prime of the form p^p+2 where p is a prime.

Conjecture: all complex roots of $\sum_{k=0}^\infty \frac{z^k}{\left(nk\right)!}$ are real

Conjecture: $$\left[n\in\mathbb{Z}^+,z\in\mathbb{C},0=\sum_{k=0}^\infty \frac{z^k}{\left(nk\right)!}\right]\Rightarrow z\in\mathbb{R}$$ This conjecture has been verified for $n\in\{1,2,4\}$. The motivation for this conjecture arose during the study of the exponential sum function which has applications to exponentiation in rings with abelian multiplication: $$\text{rues}_n\left(z\right)=\sum_{k=0}^\infty \frac{z^{nk}}{\left(nk\right)!}=\frac{1}{n}\sum _{k=1}^n \exp\left(ze^{2ki\pi/n}\right)$$

Is there a maximum number of consecutive sexy prime pair sums that are all divisible by 10?

I was finding the sums of pairs of sexy primes (prime numbers that differ by 6) and noticed that there are a lot of pairs who's sum is divisible by 10. Ex. $(7, 13)$ as $7+13=20$ and 20 is divisible by 10. I then wondered if there are consecutive sexy prime pairs who's

sum is divisible by 10 and ran some PARI/GP code to find these kind of consecutive pairs. I found upto 17 consecutive pairs divisible by 10 on PARI and tested for a search limit of 10^{12}. Here is the output I got after running my code, the first column displays the smallest prime of the lowest pair of consecutive sexy primes and the second column displays the number of consecutive pairs divisible by 10. 7 1 167 2 2237 3 2267 4 108187 5 1004057 6 3281777 7 32895377 8 65947927 9 569959037 10 602817437 11 5476396897 12 16842019627 13 16842019637 14 17004549137 15 312318208577 16 382560132847 17 This leads to my question: If there are an infinite number of sexy primes, then is there a maximum number of consecutive sexy prime pair sums that are all divisible by 10?

Infinitude of super happy primes

Similar to happy primes, I define super happy primes by the following process: (1) Find the sum of the digits raised to the power of themselves. Ex. 13 gives sum $ = 1^1 + 3^3 = 28$ (2) If the digit root of the sum is equal to 1 then it is a super happy number. Ex. digitroot(sum)$=$digitroot(28)$=1$. So 13 is a super happy prime. Here are some super happy primes I got by searching using PARI/GP with the help of user Peter. 13 19 31 61 83 89 139 157 163 193 199 313 331 383 389 571 587 613 619 631 661 68 3 691 751 839 857 863 919 983 991 1087 1117 1171 1187 1277 1399 1567 1579 1597 1 657 1663 1669 1693 1699 1747 1753 1759 1871 1933 1993 1999 2141 2281 2411 2447 Note: Since digitroot(sum) is nothing but $sum \mod 9$, the sum will be of the form $9k+1$, for some natural number k. Now coming to the question: Can we prove the infinitude of super happy primes?

There cannot be more than three primes of the form $n^{n^2}-k$ for the same k?

I was searching for primes of the form $n^{n^2}-k$ on PARI/GP and noticed that primes of this form for same k are quite rare. The probability of finding a prime of this form is $\frac{1}{n^2 \log (n)}$, which makes me believe that the number of primes for same k of this form would be finite. I also noticed that the maximum number of primes of the form $n^{n^2}-k$ for the same k seems to be three. I searched for a range of $k \le 3 \times 10^5$ and $n \le 50$ on PARI/GP and didn't find more than three primes for same k. Here are the some values of k, for $k \le 10^4$ I found on PARI/GP, that have three primes of the form $n^{n^2}-k$. The first column displays the values of k and the second column shows the values of n for which $n^{n^2}-k$ is prime. 1409 [4, 6, 8] 3083 [4, 6, 8] 5496 [5, 7, 13] 7427 [4, 6, 8] 8902 [3, 9, 15] Questions: (1) Can there not be more than three primes of the form $n^{n^2}-k$ for the same k? (2) If there can be more than three, then is there a maximum number of primes of the form $n^{n^2}-k$ for the same k? Edit 1: Following the same process, I believe that the maximum number of primes of the form $n^{n^2}+k$, for same k is four. Edit 2: Peter showed provided an example with four primes for the same k which solves my question 1. So now I only look for answers of question 2.

A really nice and elementary conjecture involving numbers

Yesterday, i discovered a nice thing while playing with numbers. It is trivial to note that $\forall n\in \mathbb{Z^+},\exists x,y\in \mathbb{Z}$ such that $3^n=5x^2+y$ has solutions. Also, undoubtedly, x,y are of different parity. But the good thing i noticed is really tough to prove i think. Conjecture If we choose to consider only the x,y such that $\mid x-y \mid$ is minimum, then if we make a table whose rows are the different values of this predefined x,y for consecutive values of n, like this where we make another row $y_{i-1}+y_i$(mainly for convenience) which will attain the sum of the current $y ~+$ the y of the previous entry. Now, interestingly, if we fix y_i, then i noticed upto $n=11$ using my calculator that $y_{i-1}+y_i\equiv y_{i+1}[5]$ (I purposely did not add the $n=11$ because i love even numbers :D But for $n=11$, $(x,y)=(188,427)$ and again $-518 \equiv 427 [5]$) I cannot understand the reason of its occurence. Can there be any elementary proof? Thanks for giving time! where the two ends of $/$ denotes congruency between the two $\mod 5$

Trigonometric integrals related to Gieseking's constant

This question at MathOverflow conjectures certain relation between fast converging hypergeometric series and Gieseking's constant. The Gieseking constant (G) is the volume of the hyperbolic 3-manifold, also called Gieseking's manifold. The hypergeometric series under consideration has trigonometric integral representations, which give two different forms of the conjecture: $$\int_0^{{\pi }/{3}} \frac{x \left({\sqrt{3}-{\sin x}}\right)\, dx}{\sin x \cdot \sqrt{3-2 \sqrt{3} \sin x}}\overset{?}{=}\frac{5}{2}\text{Im}\left(\text{Li}_2\left(e^{\frac{2 i \pi }{3}}\right)\right) = \frac{5}{3}G\tag{1}$$ $$ \int_0^{{\pi }/{3}} P(x)\, \frac{xdx}{\sin x \sqrt{\frac{3}{4}-\sin ^2x}}\overset{?}{=}5 \sqrt[4]{3}\, \rm{Im}\left(\rm{Li}_2\left(e^{\frac{2 i \pi }{3}}\right)\right) = \frac{10\sqrt[4]{3}}{3} G \tag{2} $$ where, $$P(x)=\left(\frac{\sqrt{3}}{2}-\sqrt{\frac{3}{4}-\sin ^2x}\right)^{3/2}+\left(\frac{\sqrt{3}}{2}+\sqrt{\frac{3}{4}-\sin ^2x}\right)^{3/2}$$ The 2nd representation is interesting because Lobachevsky has studied similar integrals in relation to volumes in hyperbolic geometry in his work "Application of imaginary geometry to certain integrals" (1836). Also see equation 3.842.7 in Gradshteyn and Ryzhik. For example he proves the following integration formula: $$\int_0^\beta \frac{x\sin x\, dx}{(1-\sin^2 \alpha \sin^2 x)\sqrt{\sin^2 \beta -\sin^2 x}} = \frac{\pi\ln\frac{\cos \alpha +\sqrt{1-\sin^2\alpha \sin^2\beta}}{2\cos \beta \cos^2 \frac{\alpha}{2}}}{2\cos \alpha \sqrt{1-\sin^2\alpha \sin^2 \beta}}$$ This formula in the limit $\alpha\to\pm i\infty $

becomes $$ \int_0^\beta\frac{xdx}{\sin{x}\sqrt{\sin^2{\beta}-\sin^2{x}}}=\frac{\pi}{4\sin{\beta}}\ln{\frac{1+\sin{\beta}}{1-\sin{\beta}}}.\tag{3} $$ One can see that when $\beta=\pi/3$, then both (2) and (3) have the same factor $\frac{x}{\sin{x}\sqrt{\sin^2{\beta}-\sin^2{x}}}$, and if it wasn't for the convoluted factor $P(x)$ these integrals would be the same. Lobachevsky also studied other integrals and in particular he shows that the integral with the variable upper limit $y<\beta$ $$ \int_0^y\frac{xdx}{\sin{x}\sqrt{\sin^2{\beta}-\sin^2{x}}} $$ can be expressed as a sum of elementary functions and Clausen functions. Maybe (2) is related to hyperbolic geometry and there is certain substitution that can transform this integral into a sum of Clausen functions or maybe it has some geometric interpretation? Q: How to prove conjectures (1) and (2)?

An asymptotic series for $\small\prod_{k=n}^\infty\operatorname{sinc}\left({2^{-k}}\pi\right),\,n\to\infty$

Using empirical methods, I conjectured that$^{[1]}$\!^{[2]}$ $$\small\prod_{k=n}^\infty \operatorname{sinc}\left({2^{-k}}\pi\right)=1-\frac{2\pi^2}9\,4^{-n}+\frac{38 \,\pi ^4}{2025}\,4^{-2n}-\frac{2332\,\pi ^6}{2679 075}\,4^{-3 n}+\frac{265618\,\pi^8 }{10247461875}\,4^{-4 n}+O\!\left(4^{-5 n}\right)\!.$$ Can we prove this? Can we find more coefficients in this expansion, or a general formula for those coefficients?

Does every simply-connected reductive group have trivial Galois cohomology?

Let G be a linear algebraic group over a field k with separable closure k^s and absolute Galois group $\Gamma\!_k$. Consider the Galois cohomology group $$ H^1(\Gamma\!_k,G(k^s)). $$ This group is known to be trivial in the following cases: k arbitrary, $G = SL_n$ or Sp_{2n} (Serre, Galois Cohomology, III.1). k nonarchimedean local, G semisimple and simply-connected (Bruhat-Tits). Based on these examples, we should expect the following conjecture to hold. Conjecture: Let G be a simply-connected reductive algebraic group. Then $$ H^1(\Gamma\!_k,G(k^s)) = 1. $$ Is this conjecture known to be true? Is it known to be true with additional assumptions on G or k?

Prove that $\int_0^\infty\left(\arctan \frac1x\right)^2 \mathrm d x = \pi\ln 2$

Prove $$\int_0^\infty\left(\arctan \frac1x\right)^2 \mathrm d x = \pi\ln 2$$ Out of boredom, I decided to play with some integrals and Inverse Symbolic Calculator and accidentally found this to my surprise $$\int_0^\infty\Big(\arctan \frac1x\Big)^2 \mathrm d x = \pi\ln 2 \quad (\text{conjectural}) \,\,\, {\tag{1}} $$ Here is Wolfram Alpha computation which shows (1) to be true to 50 digits. Is (1) true and how to prove it? I can calculate $$\int_0^\infty\arctan \frac{1}{x^2}\mathrm d x = \frac{\pi}{\sqrt2}$$ easily by expanding $\arctan$ into Maclaurin series. But how to proceed with $\arctan^2$?

Is $\lfloor \zeta(-n) \rfloor$ only prime for $n=23$?

I searched for primes of the form of $\lfloor \zeta(-n) \rfloor$, where $n \in \Bbb{N}$, for a range of $n \le 10^4$ on PARI/GP and found $\lfloor \zeta(-n) \rfloor$ is only prime for $n=23$. My PARI code: for(n=1, 10^4, if(ispseudoprime(floor(-bernfrac(2*n)/(2*n)))==1, print([2*n-1, floor(-bernfrac(2*n)/(2*n))])); print(2*n-1)) Note that $\zeta(-n)$ for odd n (for even n, $\zeta(-n)=0$) can be also expressed as: $$\zeta(-(2n-1))=-\frac{B_{2n}}{2n}$$ where B_{2n} is the $2n$th Bernoulli number and written as brenfrac(2*n) in PARI/GP. Questions: (1) Is $\lfloor \zeta(-n) \rfloor$, where $n \in \Bbb{N}$, only prime for $n=23$? (2) Are there finite primes of the form of $\lfloor \zeta(-n) \rfloor$? I would appreciate any counterexamples(can be a probable prime)/proofs/papers. Extra: I also searched for primes of the form $\lceil\zeta(-n)\rceil$, $\lfloor\zeta(-n)\rceil$, $\lceil B_n \rceil$ and $\lfloor B_n \rceil$. For $n \le 10^4$: (1) $\lceil\zeta(-n)\rceil$ seems to be only prime for $n=691$. (2) There seems to be no prime of the form $\lfloor\zeta(-n)\rceil$. (3) $\lceil B_n \rceil$ seems to be only prime for $n=14$. (4) $\lfloor B_n \rceil$ seems to be only prime for $n=38$.

Conjectures on the primality of $\sum\limits_{i=1}^n p_i^{p_i}$ and $\sum\limits_{i=1}^n (-1)^ip_i^{p_i}$

Inspired by Is 29 the only prime of the form p^p+2?. Claims on prime powers and their alternating sums Consider the expressions $\mathcal P=\sum\limits_{i=1}^n p_i^{p_i}$ and $\mathcal Q=\sum\limits_{i=1}^n (-1)^ip_i^{p_i}$ over the prime numbers $(p_i)_{i\in\Bbb N}$. Then I claim that $n=2,4,24$ are the only occasions when $\mathcal P$ is prime. $n=2,4$ are the only occasions when $\mathcal Q$ is prime. PARI/GP code is for(n=1,+oo,if(isprime(sum(i=1,2*n,prime(i)^prime(i)))==1,print(n))). Note that we need only check even n as all prime powers are odd excluding $p_1=2$. Frankly I have no clue where to start. However, $\mathcal P$ and $\mathcal Q$ can be represented as $$\pm2^2+3^3+x\,\text{terms of the form}\,(6k-1)^{6k-1}+(n-x-2)\,\text{terms of the form}\,(6k+1)^{6k+1}.$$ Now working in modulo 6, $$\mathcal P\equiv 4+0+x\cdot(-1)^{-1}+(n-x-2)\cdot1^1\equiv2-2x+n\pmod6$$ so $\mathcal P$ is always composite when $n\equiv2(x-1)\pmod6$. Similarly, $$\mathcal Q\equiv

-4+0+x\cdot(-1)^{-1}+(n-x-2)\cdot1^1\equiv n-2x\pmod6$$ so $\mathcal Q$ is always composite when $n\equiv2x\pmod6$. Despite this, it is difficult to verify these congruences since x can be hard to determine when n is large. Nonetheless, I suspect a modular approach like the one above is too simple to solve the problem. I would appreciate any advances on this, though I would like further values of n through computation to be made in the comments and not in the answers.

Infinite $\frac{3}{2}$-generated groups?

Let’s call a group $\frac{3}{2}$-generated iff for every $g \in G \setminus \{1\}$ there is some $h \in G \setminus \langle g \rangle$ with $G = \langle g,h \rangle$. There is a conjecture by Breuer, Guralnick and Kantor, that a finite group is $\frac{3}{2}$-generated iff all its proper quotients are cyclic. Why is the word “finite” in the conjecture necessary? Is there an infinite counterexample? If yes, what it is? A $\frac{3}{2}$-generated group with a non-cyclic proper factor? Or a non-$\frac{3}{2}$-generated group, all proper cycles of which are cyclic?

Conjectured formula for the Fabius function

The Fabius function is the unique function ${\bf F}:\mathbb R\to[-1, 1]$ satisfying the following conditions: a functional-integral equation$\require{action} \require{enclose}{^{\texttip{\dagger}{a poet or philosopher could say "it knows and replays its own future"}}}$ $\displaystyle{\bf F}(x)={\small\int_0^{2{\tiny\text{ }}x}}{\bf F}\left(t\right)dt,\,$ and a normalization condition ${\bf F}(1)=1.$ It is noteworthy that despite being smooth (class C^∞)${^{\texttip{\dagger}{i.e. continuous and having continuous derivatives of any order}}}$ everywhere, ${\bf F}(x)$ is not real-analytic at any point $x\ge0$ - its Taylor series there is either divergent, or a polynomial with a finite number of terms.${^{\texttip{\dagger}{the latter happens at dyadic rational points}}}$ Unlike some other functions that appear specifically constructed for that purpose, the Fabius function naturally occurs in research of several seemingly unrelated problems - perhaps, this is why it has been discovered and re-discovered independently many times by several mathematicians. It also has some practical applications in computational mathematics. The Fabius function ${\bf F}(x)$ is constant 0 for all $x\le0,$ but some authors prefer to define it only on $[0,\infty)$ or only on $[0,1].$ Some authors study a very closely related Rvachev${^{\texttip{\dagger}{also variously spelled as Rvachëv or Rvachyov, a.k.a. "atomic function"}}}$ function $\operatorname{up}(x)$ defined as $\operatorname{up}(x) = {\bf F}(x+1)$ for $-1\le x\le1$ and $\operatorname{up}(x) = 0$ otherwise. It is known that the Fabius function assumes rational values at dyadic rational arguments - efficient algorithms to compute those values have been published or posted online, and have been discussed on this site.$^{[1]}$$\!^{[2]}$$\!^{[3]}$$\!^{[4]}$$\!^{[5]}$$\!^{[6]}$$\!^{[7]}$$\!^{[8]}$$\!^{[9]}$ I have been looking for a non-recursive, self-contained formula for the Fabius function for quite a long time. After lots of experimentation and looking for patterns in its values I came up with a conjectured empirical formula.
Let${^{\texttip{\dagger}{the superscript m is just an index here, not to be confused with a power}}}$ $$\mathscr F^m_n = \frac1{2^{n^2}\left(\frac12;{\tiny\text{ }}\frac12\right)_n}\,\sum _{k=0}^n\frac{\binom n k_{1/2}}{2^{{\tiny\text{ }}k{\tiny\text{ }}(k-1)}(n+k)!}\,\sum _{\ell=0}^{2^k{\tiny\text{ }}m-1}\,(-1)^{s_2\left(\ell\right)}\,\left(\ell-2^km+\tfrac12\right)^{n+k}{\small,}\tag{$\small\spadesuit$}$$ where $k,\,\ell,\,m,\,n$ are non-negative integers, $\displaystyle\small\left(a;{\tiny\text{ }}q\right)_n=\prod_{k=0}^{n-1} (1-a{\tiny\text{ }}q^k)$ is the q-Pochhammer symbol${^{\texttip{\dagger}{it assumes only rational values in this formula}}}$, ${\binom n k}_q=\displaystyle\small\frac{\left(q;{\tiny\text{ }}q\right)_n}{\left(q;{\tiny\text{ }}q\right)_k\left(q;{\tiny\text{ }}q\right)_{n-k}}\vphantom{\Huge|}$ is the q-binomial coefficient${^{\texttip{\dagger}{it assumes only rational values in this formula}}}$, and $s_2(n)\vphantom{\Huge|}$ is the sum of binary digits${^{\texttip{\dagger}{i.e. the number of 1's in the base-2 representation}}}$ of n (note that $(-1)^{s_2\left(n\right)} = t_n\vphantom{\Huge|}$ is just the signed version of the Thue-Morse sequence, satisfying recurrence $t_0 = 1,\,t_n = (-1)^n \, t_{\lfloor n/2\rfloor};\vphantom{\Huge|}$ see also${^{[10]}}$${\!^{[11]}}$${\!^{[12]}}$). I conjecture that for all non-negative integers $m,\,n,$ the following identity holds: $${\bf F}\!\left({\small\frac m{2^n}}\right)=\mathscr F^m_n.\tag{$\small\diamondsuit$}$$ Note that there is no requirement for $\frac m{2^n}$ to be a proper irreducible fraction - it might well be that m is even, or $m>2^n$. I have not been able to rigorously prove it yet, but it produces exact rational values that agree with those computed using known correct algorithms for all dyadic rational arguments I have tried. Of course, this formula did not just appear out of the blue - its structure was inspired by known algorithms, and it went a long way to this relatively concise form (at some point it had about 5 levels of nested summations/products). Can we prove that $\small(\diamondsuit)$ is indeed a correct representation of the Fabius function at dyadic rationals? If the conjecture is difficult to tackle at once, we can try to at least prove that the function defined by $\small(\spadesuit)$ shares some known properties with the Fabius function, e.g.: $0\le\mathscr F^m_n\le1,$ $\mathscr F^m_n = \mathscr F^{2{\tiny\text{ }}m}_{n+1}\vphantom{\Large|}$ - the result is the same across all

representations of a rational number $\frac m{2^n}$, $\mathscr F^m_n = 1-\mathscr F^{(2^n-m)}_n\vphantom{\Large|}$ for all $\small0\le m\le2^{n}$ - rotation symmetry, $\mathscr F^m_n = \mathscr F^{(2^{n+1}-m)}_n\vphantom{\Large|}$ for all $\small0\le m\le2^{n+1}$ - reflection symmetry, for a fixed $n,$ and $\small0\le m\le2^n$ the values of $\mathscr F^m_n\vphantom{\Large|}$ strictly increase, all points $\small\left(\frac m{2^n},\,\mathscr F^m_n\right)\vphantom{\Large|}$ lie on a continuous curve - for any convergent sequence of dyadic rationals $\frac m{2^n}\vphantom{\Large|}$, the sequence of corresponding values $\mathscr F^m_n\vphantom{\Large|}$ also converges. If the conjecture $\small(\diamondsuit)$ it true, then for all $0\le x\le1$ (not necessary rational) $${\bf F}\!\left(x\right)=\lim_{n\to\infty}\,\frac1{2^{n^2}\left(\frac12;{\tiny\text{ }}\frac12\right)_n}\,\sum _{k=0}^n\frac{\binom n k_{1/2}}{2^{{\tiny\text{ }}k{\tiny\text{ }}(k-1)}(n+k)!}\,\sum _{\ell=0}^{\left\lfloor2^{n+k}{\tiny\text{ }}x-1\right\rfloor}\,(-1)^{s_2\left(\ell\right)}\,\left(\ell-2^{n+k}{\tiny\text{ }}x+\tfrac12\right)^{n+k}.\tag{$\small\heartsuit$}$$ For dyadic rational x the limit is trivial, because the sequence under the limit becomes constant for large enough n. Also, there is a known series (by Rvachev) that expresses values of the Fabius function for all $0\le x\le1$ via its values at negative powers of 2: $${\bf F}\!\left(x\right)=\sum _{n=1}^\infty\frac{(-1)^{\left\lfloor 2^n{\tiny\text{ }}x\right\rfloor }-1}{2}\,(-1)^{s_2\left(\lfloor2^n{\tiny\text{ }}x\rfloor\right)}\;\sum_{k=0}^n\frac{2^{\frac{k{\tiny\text{ }}(k+1)}2}}{k!}\,\left(x-2^{-n}\left\lfloor 2^n{\tiny\text{ }}x\right\rfloor\right)^k\;{\bf F}\!\left(2^{{\tiny\text{ }}k-n}\right).\tag{$\small\clubsuit$}$$ Again, for dyadic rational x this series terminates after a finite number of terms, producing an exact rational value.

If q is prime, can $\sigma(q^{k-1})$ and $\sigma(q^k)/2$ be both squares when $q \equiv 1 \pmod 4$ and $k \equiv 1 \pmod 4$?

This is related to this earlier MSE question. In particular, it appears that there is already a proof for the equivalence $$\sigma(q^{k-1}) \text{ is a square } \iff k = 1.$$ Let $\sigma(x)$ denote the sum of divisors of the positive integer x. Here is my question: If q is prime, can $\sigma(q^{k-1})$ and $\sigma(q^k)/2$ be both squares when $q \equiv 1 \pmod 4$ and $k \equiv 1 \pmod 4$? MY ATTEMPT Suppose that $$\sigma(q^{k-1}) = a^2$$ and $$\frac{\sigma(q^k)}{2} = b^2$$ for $q \equiv 1 \pmod 4$ and $k \equiv 1 \pmod 4$. Since $\sigma(q^k) = q^k + \sigma(q^{k-1})$, it follows that $$2b^2 = \sigma(q^k) = q^k + \sigma(q^{k-1}) = q^k + a^2.$$ Additionally, congruence-wise we obtain $$a^2 = \sigma(q^{k-1}) \equiv 1 + (k-1) \equiv k \equiv 1 \pmod 4,$$ from which it follows that a is odd, and $$2b^2 = \sigma(q^k) = q^k + \sigma(q^{k-1}) \equiv 1^1 + 1 \equiv 2 \pmod 4,$$ which implies that b is likewise odd. Now, using the definition of $\sigma(q^k)$ and $\sigma(q^{k-1})$ for q prime, we derive $$\frac{1}{2}\cdot\frac{q^{k+1} - 1}{q - 1} = b^2$$ and $$\frac{q^k - 1}{q - 1} = a^2.$$ Assume to the contrary that $$\frac{1}{2}\cdot\frac{q^{k+1} - 1}{q - 1} = b^2 \leq a^2 = \frac{q^k - 1}{q - 1}.$$ This assumption leads to $$q^{k+1} - 1 \leq 2(q^k - 1)$$ which implies that $$16 = {5^1}(5-2) + 1 \leq q^k(q - 2) + 1 = q^{k+1} - 2q^k + 1 \leq 0,$$ since q is a prime satisfying $q \equiv k \equiv 1 \pmod 4$. This results in the contradiction $16 \leq 0$. Consequently, we conclude that $a < b$. Furthermore, I know that $$(q+1) = \sigma(q) \mid \sigma(q^k) = 2b^2$$ so that $$\frac{q+1}{2} \leq b^2.$$ Finally, I also have $$\frac{q^{k+1} - 1}{2b^2} = q - 1 = \frac{q^k - 1}{a^2}.$$ Alas, here is where I get stuck. CONJECTURE (Open) If q is a prime satisfying $q \equiv k \equiv 1 \pmod 4$, then $\sigma(q^{k-1})$ and $\sigma(q^k)/2$ are both squares when $k = 1$. SUMMARY OF RESULTS SO FAR zongxiangyi appears to have proven the implication $$\sigma(q^k)/2 \text{ is a square} \implies k = 1.$$ The proof of the following implication is trivial $$k = 1 \implies \sigma(q^{k-1}) \text{ is a square}.$$ The truth value of the following implication is currently unknown: $$\sigma(q^{k-1}) \text{ is a square} \implies k = 1.$$ Together, the two results give $$\sigma(q^k)/2 \text{ is a square} \implies k = 1 \iff \sigma(q^{k-1}) \text{ is a square},$$ so that $\sigma(q^{k-1})$ is a square if $\sigma(q^k)/2$ is a square. Therefore, $\sigma(q^{k-1})$ and $\sigma(q^k)/2$ are both squares (given $q \equiv 1 \pmod 4$ and $k \equiv 1 \pmod 4$) when $\sigma(q^k)/2$ is a square.

Uniqueness of non-completable latin square of size n

It is known that partial latin squares of order n and size $n-1$ can always be completed to a latin square. I want to know if non-completable partial latin squares of order n, size n satisfy this property: There exists $n-1$ entries with the same row, column, or color. Is this a known result or maybe a false statement? If not, would it be decent for a research topic?

An arithmetic pattern

Define the odd part of a positive integer $\operatorname{od}(2^i(2j+1))=2j+1$ and define the function $f(n)=\operatorname{od}(n!-2^n)$. For $3\leq n \leq 10$ it holds that: $$f(2^n)-f(2^n-1)=2^n-2 \tag{1}$$ Does this equality holds for all $n\in\mathbb N_{>2}$? I don't like to try to prove random conjectures because I'm to bad at it, but I do like finding arithmetical patterns and test them with a computer. In the table below n and $f(n)$ are listed and the pattern is visible. Of course, there could be a rather easy explanation, only that I haven't found it. 4 1 5 11 6 41 7 307 8 313 9 2831 10 14171 11 155917 12 467771 13 6081067 14 42567517 15 638512859 16 638512873 17 10854718871 18 97692469871 19 1856156927617 20 9280784638121 21 194896477400617 22 2143861251406867 23 49308808782358109 24 147926426347074371 25 3698160658676859367 26 48076088562799171867 27 129805439119557764060 9 28 908638073836904348 4367 29 263505041412702261046859 30 395257562119053391570 3109 31 122529844256906551386796843 32 1225298442569065513867968 73 33 4043484860477916195764296871 34 687392426281245753279930 46871 35 240587349198436013647975 6640617 36 216528614278592412283178 09765621 37 801155872830791925447758961328117 38 152219615837850465835074202652 34367 39

Conjecture: No positive integer can be written as a^b+b^a in more than one way

Today, I came up with the following problem when trying to solve this. Are there distinct integers $a,b,m,n>1$ such that the equation $$a^b+b^a=m^n+n^m$$ holds? That is, is there ever an integer that can be written as a^b+b^a in more than one way? I claim that the answer is No, but I think solving this is beyond my knowledge. For a very preliminary observation, the simplest case is to consider the powers of $1,5,6,0$, since they end in those same digits. For example, $$\begin{cases}a\equiv5\pmod{10}\\b\equiv6\pmod{10}\end{cases}\implies a^b+b^a\equiv1\pmod{10}.$$ However, this brings about an issue, since there is hardly any indication as to what values x and y can take other than them having opposite parity. PARI/GP code is intfun(a,b,m,n)={for(i=2,a,for(j=2,b,for(k=2,m,for(l=2,n,if(i<>k && i<>l && j<>k && j<>l && i^j+j^i-k^l-l^k==0,print(i," ",j," ",k," ",l))))));} No solutions have been found up to $a,b,m,n\le100$.

Searching for a conjecture that is true until the 127 power of n.

I am searching for a mathematical conjecture that is true until something like n = 117, or n = 127, or a number close. It is an equality, a formula implying calcultations to the power of n, IIRC. What is the name of this conjecture ? Why do I search for this formula ?: I had read an article a few years ago that was discussing about experiments around the validation of a theory in Science, namely in Physics. The example of this conjecture was given so as to convince that you can choose to repeat an experiment with different parameters a certain number of time, ultimately in the end, it does not give the entire certainty a physical theory is true: it just happens we still haven't found any outlier measurement that contracdicts the physical theory. As a matter of fact, we can test this mathematical conjecture for the first 127 integers, which is a bunch of times, and believe it is always true, whereas it is false for all n. I would like the name of it so as to be able to name it / source it in discussion. Does it ring any bell for you ?

A conjectured value for $\operatorname{Re} \operatorname{Li}_4 (1 + i)$

In evaluating the integral given here it would seem that: $$\operatorname{Re} \operatorname{Li}_4 (1 + i) \stackrel{?}{=} -\frac{5}{16} \operatorname{Li}_4 \left (\frac{1}{2} \right) + \frac{97}{9216} \pi^4 + \frac{\pi^2}{48} \ln^2 2 - \frac{5}{384} \ln^4 2$$ I arrived at a result involving the $\operatorname{Re} \operatorname{Li}_4 (1 + i)$ term for the value of the integral while the OP is convinced the integral in question has a simple, elementary answer. If both of us are right, then the conjecture holds. So my question is, is it possible to either (i) prove the conjecture true analytically or (ii) disprove the conjecture based on (very high precision) numerical evidence?

Does there exist some prime k for which there will be exactly two primes of the form $n!+k$?

This is a question related to my recent question Conjecture: “For every prime k there will be at least one prime of the form $n!\pm k$” true? Using PARI/GP I searched for the number of primes of the form $n!+k$ possible for each prime $k\le 2300$. I observed that for some prime k, all numbers less than 24 were found except 2. Note that when $n \ge k$, $n! \pm k$ cannot be prime as k will be a factor of $n! \pm k$. This means that there are a finite number of primes of the form $n! \pm k$ for each k. User Peter and I, searched for some prime k for which $n!+k$ has two primes upto $k\le 10^5$ and found none in the range. Here is the code we used in PARI/GP if anyone wants to extend the search: forprime(k=2,10^7,s=0;for(n=1,k,if(s<3,if(ispseudoprime(n!+k)==1,s=s+1)));if(s==2,print(k))) Conjecture: For any prime k there cannot be exactly two primes of the form $n!+k$. Can prove/disprove this? Any ideas, heuristics, guesses are welcome. Update: Upto $k \le 10^6$, $k=714377$ is the only candidate remaining for which we have only found one prime of the form $n!+k$ till $n\lt 3000$. If a second prime of the form $n!+714377$ is found for the range $3000 \lt n \lt 714377$, then the conjecture is disproved!

On Composite Numbers of the Form $p_{1}p_{2} \ldots p_{k} - 1$

This question is related to D. H. Lehmer's 1932 conjecture on Euler's totient function: Are there any composite n for which $\phi(n)$ divides $n-1$? See, for example: On Lehmer's Totient Conjecture I would like to ask what is known regarding the factors of $p_{1}p_{2} \ldots p_{k} - 1$, where the p_{i} are distinct odd prime numbers? I was not able to find much in some number theory books I consulted. Thank you.

What methods show that a number is transcendental?

I've been doing a lot of research on such theories lately and these are all I've found so far: Liouvilles criterion (here) Lindemann-Weierstrass theorem (here) Gelfond-Schneider theorem (here) Brownawell-Waldschmidt theorem (here or here) Schanuels conjecture (no proof yet) (here) Six and five exponentials theorem (here) Bakers theorem (here) Roths theorem (here) Or theorems such as: If you take two transcendental numbers, a and b, then at least one of ab and $a+b$ is transcendental (here) or x^{x^x} is transcencental if $x\in\mathbb{Q}, x\notin\mathbb{N},x>0$ (here) What other methods show that a number is transcendental besides these ones? If you know any other proven or unproven theorems it would be nice to share them. Edit 1 K.Dilcher and K.B. Stolarsky (here) Carl Ludwig Siegel (here) Edit 2 The Rogers-Ramanujan continued fraction (here) is transcendental for all algebraic $-1<q<1$ All the transcendental functions (here) Edit 3 All about trancendental Infinite Products (here) (here) and (here)

Recurrence relation for the Thue-Morse sequence

I made a curious observation. Let a_n be the sequence of numbers determined by a recurrence relation $$\begin{cases} \vphantom{\large|}a_0=0\\ \vphantom{\large|}a_1=1\\ \vphantom{\Large|}n\,a_n=(5-2 n)\,a_{n-1}+3{\tiny\text{ }}(n-1)\,a_{n-2}+1 \end{cases}\tag{$\small\spadesuit}$$It also can be generated using an equivalent homogeneous recurrence relation $$\begin{cases} \vphantom{\large|}a_0=0\\ \vphantom{\large|}a_1=a_2=1\\ \vphantom{\Large|}n\,a_n = (4-n)\,a_{n-1}+(n-2)\left(5{\tiny\text{ }}a_{n-2} - 3{\tiny\text{ }}a_{n-3}\right) \end{cases}\tag{$\small\clubsuit}$$ 0, 1, 1, 2, 1, 4, -2, 13, -23, 68, -164, 439, -1146, 3067, -8231, 22306, -60791, 166684, ... It appears that this sequence modulo 2 gives the Thue-Morse sequence, meaning that if we denote $t_n=(-1)^{a_n}\,$ then it satisfies $$t_0 = 1,\quad t_n = (-1)^n \, t_{\lfloor n/2\rfloor}.\tag{$\small\diamondsuit}$$ How can we prove this?

Prime number function inequality conjecture

In my intuitive random search for conjectures I found $$n\neq 4\implies p_{n^2}\leq p_n^2<p_{4n^2}$$ It's tested for $n<1000$. I've looked at it the point of view of PNT but haven't the skills to prove or disprove it. Could there be counter examples out of reach of my conjecture seeking routines?

Any positive integer can be written as sum / difference of consecutive squares

How should one go about proving that $x \in \mathbb{N}$ can be written (with the right combination of signs) as $\pm 1^2 \pm 2^2 \pm \ldots \pm n^2$ for any $x : x, n \in \mathbb N$? I have tried for hours but can't figure out an appropriate approach. So what I ask of you specifically is, how should one be able to determine a reasonable approach for such a conjecture? Thanks.

Conjecture: ${_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};2;1 \right)=\prod_{n=2}^\infty \frac{(2n-2+x)(2n-1+x)}{2n (2n-3+2x)}$

Is the following conjecture for $0<x<1$ true and how do we prove it? $${_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};2;1 \right)=\prod_{n=2}^\infty \frac{(2n-2+x)(2n-1+x)}{2n (2n-3+2x)}$$ I encountered this function when answering a question a while back, where I have shown that: $$S=\sum_{k=1}^\infty \frac{\Gamma \left(k+ \frac{1}{2} \right)}{\Gamma \left(k+1 \right)} G_{2k-1}=\frac{\sqrt{\pi}}{2} \int_0^1 x ~{_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};2;1 \right) dx$$ Where G_k are so called Gregory coefficients. Now I returned to this problem and considered the ratio: $$\frac{{_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};n;1 \right)}{{_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};n+1;1 \right)}$$ For several cases for $n \geq 2$ Wolfram Alpha shown me the terms from the product above. This, together with an obvious identity: $$\lim_{n \to \infty} {_2 F_1} \left(\frac{1}{2}- \frac{x}{2},1- \frac{x}{2};n;1 \right)=1$$ Makes me believe that the infinite product converges. However, I don't know how to prove the ratio. Gauss's contiguous relations connect the two functions and the derivative, but I'm not sure how to use them in this case. The product is not telescoping (which is obvious, otherwise this hypergeometric function would be a rational function). Another question: are there more infinite product identities like this one for hypergeometric functions? We can rewrite the product in a more convenient way: $$\prod_{n=2}^\infty \frac{\left(1-\frac{2-x}{2n}\right)\left(1-\frac{1-x}{2n}\right)}{\left(1-\frac{3-2x}{2n}\right)}$$ Which looks a lot like a more complicated Gamma function. Claude Leibovici proposed a closed form for the product which means that the following holds: $$\sum_{k=1}^\infty \frac{\Gamma \left(k+ \frac{1}{2} \right)}{\Gamma \left(k+1 \right)} G_{2k-1}=\int_0^1 2^x \frac{x}{1+x} \frac{\Gamma \left(x+ \frac{1}{2} \right)}{\Gamma \left(x+1 \right)}~ dx$$ The series converges extremely slow, for example: $$\sum_{k=1}^{500} \frac{\Gamma \left(k+ \frac{1}{2} \right)}{\Gamma \left(k+1 \right)} G_{2k-1}=0.506676104408579236 96$$ While the integral gives: $$\int_0^1 2^x \frac{x}{1+x} \frac{\Gamma \left(x+ \frac{1}{2} \right)}{\Gamma \left(x+1 \right)}~ dx=0.507181289066845641 10$$ Which is the correct numerical value. Unfortunately, there's no in-built Gregory coefficient list in Mathematica, so it's hard to compute them for large k.

An iteration formula I found (please don't jump at me if it's already been discovered)

$\sin^2 \theta$"> Where the modulus-like symbol actually denotes iteration of a radical function. Sorry for the messy work everyone- I am new to this stuff, and I literally just found this iteration formula like 15 minutes ago. $X[i]$ starts as being an arbitrary number greater than $n!/(n-2)!$ which I should have mentioned earlier but didn't have space to (apologies). So the business is: you start with a number e.g. 1, then if you want to find say 50, you compute $sqrt(1 + 50!/48!)$ then replace 1 on your calculator with the result you just got a.k.a. Ans etc. and keep iterating till you get (at a surprisingly fast convergence rate!) the very number you started with, n. I appreciate this might not be the most interesting insight or $n!/(n-2)!$ is probably just me not realising that it could also be presented as $n(n-1) = n^2-n$. But still, please don't mass-downvote it all, remember it's a 15-year old person who figured this out...

Conjecture $\sum_{n=0}^\infty a_n= \frac{1}{2}-\frac{7 \zeta(3)}{2 \pi^2}$

Working with some integrals I stumbled upon the following slowly converging series: $$ S = \sum_{n = 0}^{\infty}\left(-1\right)^{n} \left[n + \frac{3}{2} + \left(n + 1\right)\left(n + 2\right) \log\left(1 - \frac{1}{n + 2}\right)\right] $$ I have reasons to suspect that the series has a closed form: $$S=\frac{1}{2}-\frac{7 \zeta(3)}{2 \pi^2}=0.073721601182494209 \ldots$$ The actual proof eludes me so far. Can you prove or disprove this conjecture? Writing the logarithm as a series we have: \begin{align} &\left(n + 2\right) \log\left(1 - \frac{1}{n+2}\right) = -\sum_{k = 1}^{\infty} \frac{1}{k\left(n + 2\right)^{k - 1}} \\ = &\ -1-\sum_{k=1}^\infty \frac{1}{(k+1) (n+2)^k} \end{align} Which turns the series into: $$S=\sum_{n=0}^\infty (-1)^n \left(\frac{1}{2}-(n+1) \sum_{k=1}^\infty \frac{1}{(k+1) (n+2)^k} \right)$$ I can provide the way I came to this expression, but it's very long and complicated, as usual. I'd like some clear proof, if possible. To get the sense of how slowly the series converges, for 20000 terms the result agrees with the stated closed form in 4 first significant digits. The integral from which this series was obtained is (again, conjectured): $$\int_0^1 {_2 F_1} (1,-t;2-t;-1) dt = \frac{7 \zeta(3)}{\pi^2}+\frac{1}{2}$$ I don't think it's very useful, except for numerical confirmation.

Conjecture on Prime Numbers and Exponential Equipment

How to generate a rigorous proof for - The specific conjecture which states that we can always frame every Prime number in an exponentially framed equation with perfect cubes & squares. I'll present the respective segments of the conjecture and its Prototype. Conjecture's statement - The square of every Prime number can be expressed as a sum or difference of some perfect cube and any another Prime Mathematical Structure $a^3 \pm P_{k} = P^2_n$, $a,n, k\in\mathbb{N}$, Where P_m denotes the mth Prime respectively . Progress on Initial inputs and outputs- $\begin{array}{||c || c ||} \hline a^3 \pm p_k& p_n^2 \\ \hline 1+3& 2^2\\ \hline 512-503& 3^2\\ \hline 8+17& 5^2\\ \hline 8+41& 7^2\\ \hline 8+113& 11^2\\ \hline 216-47& 13^2\\ \hline 8+281& 17^2\\ \hline 8+353& 19^2\\ \hline 8+521& 23^2\\ \hline 1728-887& 29^2\\ \hline 8+953& 31^2\\ \hline 8+1361& 37^2\\ \hline 1728-47& 41^2\\ \hline 8000-6151& 43^2\\ \hline 216+1993& 47^2\\ \hline 8+2801& 53^2\\ \hline 512+2969& 59^2\\ \hline 512+3209& 61^2\\ \hline 8+4481& 67^2\\ \hline 1728+3313& 71^2\\ \hline 216+5113& 73^2\\ \hline 1728+4513& 79^2\\ \hline 216+6673& 83^2\\ \hline 8000-79& 89^2\\ \hline ...\pm...& 97^2\\ \hline ...\pm...& 101^2\\ \hline ...\pm...& 103^2\\ \hline \end{array}$ Conjecture's Prototype The sum or difference of

square of every Prime Number with some Perfect cube yields any another Prime number. Mathematical Structure $(m^3 \pm P^2_{b} = P_c)$, $m,b,c \in\mathbb{N}$ and P_n is the nth Prime Number respectively. The above parent equation can be framed in other 3 ways aslike - $P_c - m^3 = \pm P^2_b$ which clearly generates the expression for square of every Prime number as per the conjecture constraints. $|P_c - m^3| = |P^2_b|$ where taking modulus yields positive results, $P_c \mp P^2_b =m^3$ Initial inputs and outputs- $\begin{array}{||c || c ||} \hline P_c - m^3 & \pm P_b^2 \\ \hline\hline 31-27& 2^2\\ \hline 17-8& 3^2\\ \hline 89-64& 5^2\\ \hline 113-64& 7^2\\ \hline 337-216& 11^2\\ \hline 233-64& 13^2\\ \hline 353-64& 17^2\\ \hline 577-216& 19^2\\ \hline 593-64& 23^2\\ \hline 887-1728& -29^2\\ \hline 2689-1728& 31^2\\ \hline 1433-64& 37^2\\ \hline 1063-2744& -41^2\\ \hline 1913-64& 43^2\\ \hline 2273-64& 47^2\\ \hline 3023-5832& -53^2\\ \hline 3697-216& 59^2\\ \hline 5449-1728& 61^2\\ \hline 6217-1728& 67^2\\ \hline 8783-13824& -71^2\\ \hline 5393-64& 73^2\\ \hline \end{array}$ The parameter a in Primary conjecture and the parameter m in its prototype takes infinitely many but unique values . In order to prove it , one needs to overcome a new level of challenges it brings in Number theory , So far many efforts have been made to prove the Conjecture but we couldn't prove it for every value of a & m respectively. Aops community on internet has made efforts on it here Providing hypothesis... Proving a special case ... Hope we get to see a well defined constructive proof which even generalizes the Special case within itself.

Determinant Optimization Conjecture

Let the maximum value of $n \times n$ determinant with $n \in\mathbb{N} >1$ be D_n . If each of the elements in determinant is either $+1$ or -1 , Then the successive values of D_n makes a Geometric Progression . D_2 $\begin{vmatrix} 1&-1 \\ 1&1 \\ \end{vmatrix}=2$ D_3 $\begin{vmatrix} 1&-1&\pm1 \\ 1&1&-1 \\ 1&1&1 \end{vmatrix}=4$ D_4 $\begin{vmatrix} 1&-1&1&-1 \\ 1&-1&-1&\pm1 \\ 1&1&1&-1\\ 1&1&1&1\\ \end{vmatrix}=8$ D_5 $\begin{vmatrix} 1&1&-1&-1&1 \\ -1&1&-1&1&1 \\ 1&1&1&1&1\\ -1&1&1&1&-1\\ 1&-1&1&1&-1\\ \end{vmatrix}=16$ D_6 $\begin{vmatrix} 1&-1&1&1&1&1 \\ 1&1&1&-1&-1&-1 \\ 1&1&1&-1&1&1\\ -1&-1&-1&1&1&-1\\ 1&1&1&1&-1&-1\\ -1&-1&1&1&1&1\\ \end{vmatrix}=32$ And so on... CRUX - Optimization- The determinant being optimized to maximum value always yields a number which follows up a geometric progression , Why isn't it even a bit higher or lower than it , to remove our this specific qualm , it's always saturated to a G.P. and strictly follows the same algorithm . Next thing is the Result of the Optimized Determinant - D_n $=$ Always a G.P. , how does it strictly follow up being a G.P. , suppose that we frame it algebraically , then will it show the same behavior ?! It's very necessary for algebraic frameworks . Configuration- Where to plot the elements so that in order to optimize it ?! The order increases ... So does the difficulty. Does it holds true for even more than 2 elements ?! And will it also yield G.P. as output ? Can we also have negative numbers and later non-integral Reals & which also follows the same G.P. tradition ?! Configuration also includes the order of configuration of the determinant itself , so can we have $n\times n$ type determinant with at most 2 distinct elements which follows the same above argument ?! Till now we saw that as the order of the determinant increases , the difficulty in optimization & it's respective element's configuration also increases ... Generalization- Generalizing it & framing it to a well finished conjecture ! Yes , but there always exists the Qualm about optimization & configuration issues as per mentioned above ... I did tried distinct elements - 1 & 2 this time , and surprisingly it came out to generate Geometric progressive numbers as output ! Holy Jesus ! Before generalizing one should keep all the above issues in mind & Is it a NP-HARD /COMPLETE problem which I end up with? ... Proof Positive- The ultimate explanation for this Enigmatic behavior of such determinant's optimization and it also includes the strict algorithm for the configuration of elements and generation of the final & the absolute proof dealing with all the above arguments. My dear colleague mrtaurho has made significant efforts towards the conjecture and I'll phrase his words here , and that'll count in the latest progress made in my conjecture over the sphere of internet. [Source - Aops community Forum named - Mathematics Research Station] mrtaurho's article - As brilliantly found by Alphatrion there are some matrices of size $n\times n$ of the given type with a determinant precisely 2^{n-1}. However, this value is far away from being maximal. I have not found a version of D_3 with determinant $\geqslant4$ but for all values $n>3$ (we may distinguish between odd and even n) it is worth considering matrices of the type $$D_{2k+1}^*=\begin{pmatrix}-1&\dots&1\\1&\ddots&\vdots\\1&\dots&-1\end{pmatrix}~~~D_{2k}^*=\begin{pmatrix}1&\dots&-1\\1&...&\vdots\\-1&\dots&1\end{pmatrix}$$ For those we gain $D^*_4=2^4=16,~D^*_5=s^4\cdot3=48,~D^*_6=2^7,~D^*_7=2^6\cdot5,~D^*_8=2^8\cdot3,~D^*_9=2^8\cdot7,\dots$ from where one can guess that in general we have $D^*_n=(n-2)2^{n-1}$ which is clearly greater than 2^{n-1} alone. This seems to work out but I have no idea how to prove this relation. [Small Remark: sticking to the type D^*_n given for odd n the formula changes to $D_n^*=(-1)^{n-1}(n-2)2^{n-1}$; so the alternate form for even n is just for aesthetics]. I have found the values using this online calculator Another observation worth being mentioned: $|D_n|\leqslant|D_{n+1}|$. This is quite simple by using block matrices as we have that $$|\det(D^\star_n)|=\left|\begin{pmatrix}\mathbf{1}&\mathbf{0}\\\mathbf{0}&\mathbf{D_{n-1}}\end{pmatrix}\right|=|1\cdot\det(D_n)|=|\det(D_n)|$$ And given D_n^* we know that there are configurations for D_n whose determinant exceeds D_{n-1}. To end this post I would like to mention Leibniz Formula for Determinants which states that $$\det(A)=\sum_{\tau\in S_n}\operatorname{sign}(\tau)\prod_{i=1}^na_{i,\tau(i)}$$ Here τ is a permutation of the symmetric group (on n letters) S_n and $\operatorname{sign}(\tau)$ returns the sign of the permutation τ. Note that there are precisely $|S_n|/2=n!/2=|A_n|$ even and thus $n!/2$ odd permutations. However, I do not see how one may apply this formula here but I thought it may be good to have it linked here. So the above article ends up here and the contribution of user Zatanna on Aops (which he gave values of D_5 & D_6 have been merged) . I choose ±1 to initially explain my observations because it's easier than picking up any other set of elements available to us, The results holds true for other specific cases too. n^{th} Dimensional Prime Nexus Conjecture (Hamilton's Path & Cycle)

The system and proposition of Prime Nexus - We have to arrange $n>1$ Distinct natural numbers in a sequence such that the adjacent elements sums upto any Prime number. Convenience is when we set this problem to Graph Theoretic setting and specifically by using Hamilton's path and cycles. This system of clusters of natural numbers summing upto primes is called the Prime Nexus . Leave the question that at which extent it's helpful , likewise if the numbers are more then it starts getting tough . n^{th} Dimensional Prime Nexus Conjecture We can always generate any regular & definite n-th dimensional shape out of the nexus of Primes , specifically out of the Hamilton's path such that the nodes sums upto any Prime number. Suppose in order to arrange Distinct natural numbers in a sequence such that their adjacent elements sums upto any prime , we can have $1D$ Shape , $2D$, $3D$ and so on... generated out of the nexus , (Preferring the extension of squares & cubes...) I've worked out till $3D$ (can also replace 1 by 9 In $3D$) as the number of numbers increases in the cluster , the probability of getting more higher dimensional nexus gets increased. I strongly believe that the system never saturates at any k^{th} dimension. So If someone comes up with any counter example, actually he/she hasn't ! Because if we try generation of prime nexus for more higher number of numbers , we can always do that ! Please lemme know your opinions on it , how could anyone explain this enigmatic behavior of prime numbers making up higher dimensional shapes... And how could anyone even attack this conjecture! I'm very excited to learn new things regarding this conjecture, Everyone else here on MSE community holds more knowledge that I do , so please forgive me for any inconveniences followed up in presentation of my contents here. Regards

Conjecture: Any sufficiently big sum of three squares can be written as a square sum of three different natural numbers greater than zero

A natural number can be written as a sum of three squares if and only if it's not of the form $4^m(8n+7)$ for natural numbers m,n. I'm curious about such numbers that can be written as the square sum of three different natural numbers >0. My conjecture is: Any sufficiently big sum of three squares can be written as a square sum of three different natural numbers greater than zero. That is, there is a largest number $a^2+b^2+c^2$ which can not be written so that $0<a<b<c$. I would like to see a proof or a counter-proof or a related reference request. See also Primes of the form $a^2+b^2+c^2$, $0<a<b<c$

Manipulating sets into periodic sets

Consider the set $[0,1,1,0,1,0,1,0,0,0,1,...]$. The nth element in this set is equal to 1 if n is prime and is else equal to 0. Here are my question: Is this Set non-periodic (If you write it as the fractional part of a binary number, the number is irrational)? To me it seems pretty obvious, because if it would be periodic we would have formula for the nth prime, but i cant come up with a explicite proof If we turn an infinite amount of 1's into 0's so that the set still contains of an infinite amount of 1's, can we create an periodic set? I think the answer is no, but i cannot come up with a proof of this either

Is there a Collatz 'branch' stopping time equation?

Definitions: -Collatz: odd: $\frac{3x+1}{2}$ | even: $\frac{x}{2}$ -Branch: Starting at an odd number and increasing until reaching an even number. Then decreasing until reaching another odd number (ex: 7,11,17,26,13 -> 4 steps). Question: As far as I'm aware, there is not an equation where one can plug in a specific starting number and get the stopping time of Collatz for that number, but is there a known equation that gives the stopping time for the first 'branch' of Collatz for a given number (or in the case of 5, the full stopping time)?

$\int_{0}^{\infty}\sin({x f({x})}) d x$ converges for positive monotone increasing unbounded continuous $f({x})$

Let a continuous speed function $f:\mathbb{R}^+\to\mathbb{R}^+$ exist such that $[{\{a,b\}\subseteq\mathbb{R}^+\land a<b}] \Rightarrow f(a)<f(b) $. Then $\int_{0}^{\infty}\sin({x f({x})}) d x$ converges. Looking at the positive and negative parts in pairs, if the integral starts with a positive chunk, the integral is positive, and if the integral starts with a negative chunk, then the integral is negative. Thus the first chunk is an upper bound if the chunk is positive, and the first chunk is a lower bound if the chunk is negative. The chunks approach zero because $f(x)\to\infty$ as $x\to\infty$, thus the upper and lower bounds approach each other. My problem with this argument is that even though this argument is obvious, the argument seems non-rigorous. I need the proof to convince Wolfram staff about a bug report: Integrate[Sin[x*Log[x+1]], {x, 0, Infinity}] is claimed to not converge because it converges too slowly.

A pattern on finding squares for which their sum is $\Big(\sum\limits_{i=0}^j x^i\Big)^2$

Apologies for the inactivity. I haven't been doing so well in life, lately, but I'm glad to be back at some maths! Here's a pattern I discovered. I'm not good at explaining with words, so hope you get it. It shouldn't be too difficult. Can it be proven? For all $x\in\mathbb{R}$, $$\begin{align}\bigg(\sum_{i=0}^1 x^i\bigg)^2&=x^2+2x+1\\ &=(x+1)^2\end{align}$$ $$\begin{align}\bigg(\sum_{i=0}^3 x^i\bigg)^2&=x^6+2x^5+3x^4+4x^3+3x^2+2x+1\\ &=(x+1)^2+2(x^2+x)^2+(x^3+x^2)^2\end{align}$$ $$\begin{align}\bigg(\sum_{i=0}^5 x^i\bigg)^2&= x^{10} +2x^9+3x^8+4x^7+5x^6+6x^5+5x^4+4x^3+3x^2+2x+1\\ &=(x+1)^2+2(x^2+x)^2+3(x^3+x^2)^2+2(x^4+x^3)^2+(x^5+x^4)^2\end{align}$$ Clearly there is a pattern with the exponents in the square of each partial sum, as well as the coefficients. Can one prove this pattern continues ad infinitum? For $\sum\limits^j$ I think the pattern also applies to even j and not just odd j as shown above, but I wrote this all on a napkin as I was eating at a restaurant, and now I've lost the napkin. (True story.) Any help would be much appreciated. Thank you :)

Rare gaps between integers having the same number of co-primes

Let $\varphi(x)$ be the Euler totient function. For $k = 1,2,3,\ldots$ I calculated the number of solutions of $\varphi(x) = \varphi(x+k)$. I observed that we have very few solutions when $k = 3,9,15,21,\ldots$ and a very large number of solutions when $k = 6,12,18,24,\ldots$ as shown below for $n \le 10^7$. Question 1: Why do we have a very few solutions when k is an odd multiple of 3 and a very large number of solutions when k is an even multiple of 3? Question 2: Is the following claim true? For any six consecutive positive integer values of k, and a sufficiently large x, the number of integers $n \le x$ such that $\varphi(n) = \varphi(n+k)$, is the lowest when $k \equiv 3 \text{ (mod 6)}$ and is the highest when $k \equiv 0 \text{ (mod 6)}$. Related question: Gap between integers having the same number of co-primes

Can this heuristic argument be useful to prove: Sum of digits of a^b equals ab conjecture?

I've been trying to write a proof for the following conjecture (from this question): Let $s\left(a^{b}\right)$ denote the sum of the digits of a^{b} in base 10. Then the only integer values a,$b>1$ that satisfy $s\left(a^{b}\right)=ab$ are $(2,2),(3,3),(3,6),(3,9)$ and $(3,27)$. I found what I think is a heuristic argument, but i'm not sure if it can be useful in proving the conjecture. Let $d\left(n\right)$ denote the number of digits of integer n in base 10: $$d\left(n\right)=1+\left\lfloor \log_{10}n\right\rfloor $$ Let $s\left(n\right)$ denote the digit sum of integer n in base 10. Now from the conjecture, take for example the case $a=2$. I've been looking at the following sum: $$\sum_{n=1}^{b}\frac{s\left(2^{n}\right)}{\sum_{k=1}^{n}d\left(2^{k}\right)}$$ The plot of that sum for $1\leq b\leq20000$ looks like that: And now the same plot, with in orange, $9\log b$: The difference between the 2 curves quickly converges to a value c, and we see that: $$ \lim_{b\rightarrow\infty}\left(9\log b-\sum_{n=1}^{b}\frac{s\left(2^{n}\right)}{\sum_{k=1}^{n}d\left(2^{k}\right)}\right)=c\approx12.721\ldots $$ From this, we can also conclude that: $$ \frac{s\left(2^{b}\right)}{\sum_{k=1}^{b}d\left(2^{k}\right)}\sim9\log\left(\frac{b-1}{b}\right)\sim\frac{9}{b} $$ And since: $$ d\left(n\right)=1+\left\lfloor \log_{10}n\right\rfloor \approx1+\log_{10}n $$ Then: $$ \sum_{k=1}^{b}d\left(2^{k}\right)\approx\frac{b^{2}\log_{10}2}{2} $$ And: $$ s\left(2^{b}\right)\sim\left(\frac{9}{b}\right)\left(\frac{b^{2}\log_{10}2}{2}\right)\sim\left(\frac{9}{2}\right)b\log_{10}2s\left(2^{b}\right)\sim1.3546\times b $$ The same applies to other values of a, so more generally: $$ s\left(a^{b}\right)\sim\left(\frac{9}{2}\right)b\log_{10}a $$ Looking at plots of $s(a^b)$ for each values of a from 2 to 8, we can see this asymptotic relation seems to be very accurate. Now I have 2 questions: 1: Does the asymptotic relation above is correct, or is there some errors in my reasoning? 2: Since $a>\left(\frac{9}{2}\right)\log_{10}a$, does an asymptotic relation like that is enough to prove $s\left(a^{b}\right)<ab$, for sufficiently large b? Any help or advice would be appreciated.

Yet a conjecture about the prime counting function.

This is a conjecture emanating from random tests with my set routines written in Forth. $a>b \;\wedge \pi(a+b)=\pi(a)+\pi(b)\implies b<11$ Furthermore, if $b\in\mathbb N$, then $b\in\{0,1,2,3,4,9,10 \}$ I would like (partly) proofs or counterexamples. Tested for $b<a<100,000$. Testing the numbers of hits for the non trivial values of b and for some upper limits: 1 2 3 4 9 10 100 74 48 8 14 2 2 1000 832 332 34 66 4 6 10000 8771 2454 204 406 11 20 100000 90408 19180 1223 2444 37 72 1000000 921502 156992 8168 16334 165 328

Convergence of Laplace transform

Suppose that $F: \mathbb{C} \to \mathbb{C}$ is analytic when $\operatorname{Re}(z)>0$. Assume that it is possible to show that F can be represented as a Laplace transform $$ F(z) = \int_0^{ + \infty } {\rm e}^{ - zt} f(t)\,{\rm d}t, $$ for $\operatorname{Re}(z)>a$ with some non-negative constant a and f being analytic in a neighbourhood of the positive real line. Does it follow from the analyticity of F for $\operatorname{Re}(z)>0$ that $a=0$?

Some lesser known open problems/ conjectures in number theory

What are some lesser known problems/ conjectures in number theory (especially on prime numbers) which have evolved in these recent years and didn't got much of attention, and obviously wasn't featured in any global mathematical mainstream , It includes equivalences of pre existing conjectures/ results... Please let me know, thanks in advance

Prime twins $ (3^n - 2, 3^n - 4) $ conjecture

Let n be a positive integer. Conjecture There are infinitely many prime twins of the form $$ (3^n - 2, 3^n - 4) $$ Examples include $$(3^2 - 2,3^2 - 4) = (7,5) $$ $$ (3^{37} - 2 , 3^{37} - 4) $$ $$ (3^{41} - 2 , 3^{41} - 4) $$ Notice $2,37,41$ are primes themselves. Coincidence ? This resembles conjectures about prime twins , fermat primes and mersenne primes. So I do not expect a proof :) I already know the typical statistical arguments why this should be false (zeta(2) type sums as expected amount) , so I Will not ask for that either. My mentor believes this. How many values are known apart from these ? Are there equivalent conjectures known ? Is a disproof possible ? I was not able to disprove it. I tried mod arguments. Any ideas ?

Does this procedure always generates at least one prime?

Suppose that p_n is the n-th prime and $n \neq 1,2$. To every p_n we can associate $(n-2)$-tuple $(2p_n+p_{n-1},...,2p_n+p_2)$ and from some calculations that I have done it seems that it could be that at least one of the numbers from that $(n-2)$-tuple for every p_n is a prime number. Is that true?

Has this basic number theory conjecture been discovered or proved before?

So I was sitting in a car bored for two hours playing around with the calculator on my phone, and I discovered that by picking two numbers (at least one being odd and both being not divisible by each other) I could always add them together to make many different numbers. Furthermore, I could always add and subtract them together make 1; this is significant because I could then negate and indefinitely duplicate the series to create any positive and negative integers. Here are some examples: 8-7=1 16+16+16+16-9-9-9-9-9-9-9=1 17+17+17-5-5-5-5-5-5-5-5-5-5=1 and so on. For convenience, I preferred to write these equations in the form a*x-b*z=1 8*1-7*1 = 1 16*4-9*7 = 1 17*3-5*10 = 1 Here is my Conjecture: Any two non-zero integers indivisible of each other, if at least one of them is odd, can be added or subtracted together indefinitely to make any integer. Another way of writing it (though it is more limiting) is this: Given that a and b are two non-zero integers indivisible of each other, if at least one of them is odd, there always exists some value of x and z for any given integer n that makes the equation ax-bz=n true. My question is, has anyone ever discovered or proved this conjecture before, and how can it be proven? It almost feels like the solution should be as obvious as the equation a*x-b*z=0 (which just requires finding the lcm of the two numbers) and that it's just a simple quirk in numbers based upon the already laid down basic laws of mathematics.

If $q^k n^2$ is an odd perfect number with special prime q, then can $n^2 - q^k$ be a cube?

Let $q^k n^2$ be an odd perfect number with special prime q satisfying $q \equiv k \equiv 1 \pmod 4$. This question is an offshoot of the following earlier post: If $q^k n^2$ is an odd perfect number with special prime q, then $n^2 - q^k$ is not a square. My question in the present post is the following: If $q^k n^2$ is an odd perfect number with special prime q, then can $n^2 - q^k$ be a cube? Not much can be said without some additional hypotheses. In the paper titled Improving the Chen and Chen result for odd perfect numbers (Lemma 8, page 7), Broughan et al. show that if $$\frac{\sigma(n^2)}{q^k}$$ is a square, where $\sigma(x)$ is the sum of divisors of $x \in \mathbb{N}$ and $q^k n^2$ is an odd perfect number with special/Euler prime q, then $k=1$. It follows that, if $\sigma(n^2)/q^k$ is a square, then $\sigma(n^2) \equiv 1 \pmod 4$, which implies that $q \equiv k = 1 \pmod 8$. Since n is odd, $n^2 \equiv 1 \pmod 8$. This implies that $8 \mid (n^2 - q^k)$. Alas, this is where I get stuck. I do not even know how to rule out the simplest case $$n^2 - q^k = 8.$$ An Elementary Attempt to Rule Out $n^2 - q^k = 8$ Subtract 9 from both sides, and transfer q^k to the RHS: $$n^2 - 9 = q^k - 1.$$ Factoring both sides, we get $$(n+3)(n-3)=(q-1)Q$$ where $Q=\sigma(q^{k-1})$. We get two cases: Case 1 $n+3 \mid (q^k - 1)$ This implies that $n + 3 \leq q^k - 1$, from which we obtain $$n < n + 4 \leq q^k.$$ But we know from work of Brown (2016), Dris (2017), and Starni (2018) that $q < n$ holds unconditionally. Thus, we get $$q < n < q^k$$ which contradicts $k=1$. Case 2 $n - 3 \mid (q^k - 1)$ This implies that $$n - 3 \leq q^k - 1$$ which means that $$n - 2 \leq q^k.$$ Again, by the results of Brown, Dris, and Starni, we have $$q - 2 < n - 2 \leq q^k,$$ which does not contradict $k=1$. Can anything be said about the general case, preferably by relaxing the hypotheses? UPDATE (1 NOV 2019 - 08:32 AM Manila time) Blimey! I did not realize that Case 1 $n+3 \mid (q^k - 1)$ holds in general. Thus, under the assumption that $\sigma(n^2)/q^k$ is a square, $n^2 - q^k \neq 8$.

Why is that a conjecture is written and its proof can not be done for years?

Why is it that if a conjecture is written and its proof can not be done for years, means if its statement is understandable in language, why is the proof not possible if the conjecture is correct? E.g., the proof of Fermat's last theorem (which was very clear what is it saying) was done 350 years later than it was conjectured and it took 130 pages. Fermat couldn't think for 130 pages and then give the conjecture. So why is the proof so horrible for such simple equation?

Conjecture to start a proof

In an inductive proof example, my book starts with the identity stating $$\sum\limits_{i=1}^n \sum\limits_{j=1}^i j = \frac{n(n+1)(n+2)}{6}\;.$$ As a sidenote, it says they reached this identity by conjecture, calculating the double sum for low values of n. How on earth did they see this? I attempted this expansion (don't know if it's right): $$\sum\limits_{i=1}^n \sum\limits_{j=1}^i j = \sum\limits_{i=1}^n (1 + 2 +\ldots+i) = 1 + 2 + \ldots + \sum\limits_{i=1}^n i = 1 + 2 + \ldots + (1 + 2 + \ldots + n)\;.$$ From this, I don't see how they arrived at the fractional cubic polynomial. Any help would be appreciated! Thanks.

For all $n\in\mathbb{N}$ with $n>1$ there exists an $m\in\mathbb{N}$ with $m<n$ such that $mn+1$ is prime.

I was using Python to explore some interesting lexicographically earliest sequences. I was looking into the sequence of numbers such that $a(1)=1$ and $a(n)$ is the smallest number such that $a(k)n+1$ is not prime for any $k<n$. After computing this sequence, it appeared to be exactly the odd integers. The absence of even integers interested me, as that suggested that for every even integer n there exists an odd $m<n$ such that $mn+1$ is prime. After checking with Mathematica, this appeared to be true. In fact, this suggested the more general conjecture in the title: For all $n\in\mathbb{N}$ with $n>1$ there exists an $m\in\mathbb{N}$ with $m<n$ such that $mn+1$ is prime. This doesn't sound too difficult, but then again there are plenty of nice-sounding prime conjectures that remain unsolved, so this could be one of those. How could this be proven? And if its unsolved / really difficult, what is the name of the conjecture?

Does "finite average" exist?

I will call an average any continuous function $f(v_1,\dots,v_n)$ of n arguments such that it lies in the closed interval $[\min(v_{1},\dots ,v_{n});\max(v_{1},\dots ,v_{n})]$, is symmetric for all permutations of arguments, and is homogeneous with the degree 1. Question: Can an average not to tend to infinity when one of the arguments tends to infinity and the rest arguments are fixed nonnegative reals? (We can assume $n\geq 2$.) My original question had a trivial solution $\min(v_{1},\dots ,v_{n})$, so let's add an additional requirement: our average not to tend to zero when one of the arguments tends to zero and the rest arguments are fixed positive reals? (We can assume $n\geq 2$.)

V3-019033 | MSE-3452562

Does “smooth finite average” exist?

(That question was answered. I realized I asked a wrong question. So here is a modified question.) I will call an average any continuous function $f(v_1,\dots,v_n)$ of n arguments such that it lies in the closed interval $[\min(v_{1},\dots ,v_{n});\max(v_{1},\dots ,v_{n})]$, is symmetric for all permutations of arguments, and is homogeneous with the degree 1. Question: Can an average provided the below additional requirements (I ask for the case if all of them are required but also for milder cases of just a part of these requirements) not to tend to infinity when one of the arguments tends to infinity and the rest arguments are fixed nonnegative reals? (We can assume $n\geq 2$.) Our average does not tend to infinity when all arguments except one tend to infinity. Our average is C^1-smooth in every argument (maybe except the argument(s) value equal to zero). Our average is C^∞-smooth in every argument (maybe except the argument(s) value equal to zero).

Lower bound for the n-th record gap between primes in an arithmetic progression

(This is a natural counterpart to question 3132001 which deals with upper bounds.) Let q and r be coprime integers, $1\le r < q$, and consider the arithmetic progression $$ r, \ r+q, \ r+2q, \ r+3q, \ldots \tag{P} $$ Dirichlet proved that there are infinitely many primes in progression (P) when $\gcd(q,r)=1$. This is Dirichlet's theorem on arithmetic progressions. Let $R(n,q,r)$ be the nth record gap between primes in progression (P). For example, with $q=6$ and $r=5$, we have $R(n,6,5)=\mbox{A268928}(n)$; see http://oeis.org/A268928. Conjecture: Almost all record gaps $R(n,q,r)$ satisfy $$ R(n,q,r) > {1\over6} \varphi(q) n^2. \tag{L} $$ Here $\varphi(q)$ is Euler's totient function. Question: Find counterexamples to inequality (L). (Please find as many as you can. You will likely need to write a program and run it long enough.)

Conjecture: smallest missing mod value always yields previous prime

I've come up with a conjecture that seems similar in strength to Legendre's or Oppermann's, but maybe subtly different. Let a_n be the smallest nonnegative value such that there is no m in $1<m<n/2$ where $n \equiv a_n \pmod m$. Then for all $n>2$, we have $n-a_n=p_{\pi(n)-1}$, the closest previous prime to n. Take $n=16$ as an example: $$\begin{eqnarray} 16 &\equiv 0 \pmod 2 \\ &\equiv 1 \pmod 3 \\ &\equiv 0 \pmod 4 \\ &\equiv 1 \pmod 5 \\ &\equiv 4 \pmod 6 \\ &\equiv 2 \pmod 7 \end{eqnarray}$$ The smallest value not seen is $a_n=3$, and $16-3=13$ is the previous prime. In cases where n itself is prime, e.g. 17 yielding the values $\{1,2,1,2,5,3,1\}$, you can either interpret 0 as the missing value and 17 as the prime, or 4 giving $17-4=13$. (I'm not sure which is the more consistent interpretation.) I've verified this empirically through 10^5, but cannot come up with a proof. In fact, I suspect a proof would be very difficult since what this seems to come down to is whether there is always a prime in the interval $(n,n+d)$ for a composite n, where d is the largest proper divisor of n. This has its worst case for forms of p^2, which seem to require a prime in $\left(p^2, p(p+1)\right)$. Note that when $a_n < \lfloor \sqrt{n} \rfloor$, it is easily provably true; the problem is you can't guarantee it will be in that range, despite the fact that it almost certainly is for all $n \geq 127$. I'm curious whether this conjecture already exists somewhere or is actually equivalent to one of the better-known prime gap conjectures. Better yet would be a proof, but that's obviously wishful thinking.

Justification for the conjectures on self-avoiding walks

There are two conjectures on self-avoiding walks that I haven't seen any justification of. One is the asymptotic growth of the number of length n self-avoiding walks, the form I've seen most often is $$ c_n \sim A\mu^n n^{\gamma-1}, $$ where A, μ, γ are constants. Of all the literature I've seen, I haven't read about any justification for this formula, rigorous or not. The other conjecture is stated in the Wikipedia page for self-avoiding walks and says that finding the number of such walks in a given lattice is NP-hard. There was no citation given for this, so I must ask where does this assertion appear in the literature. Edit: Any papers referencing the NP-hardness conjecture should be about counting SAWs in the lattice $\mathbb{Z}^2$ or $\mathbb{Z}^n$

p, q and $\sqrt[n]{p} + \sqrt[n]{q}$ are rational, with the latter being non-zero. Are $\sqrt[n]{p}$ and $\sqrt[n]{q}$ rational?

Let $p, q \in \mathbb Q$, $n \in \mathbb Z^+$ and label $a = \sqrt[n]p, b=\sqrt[n]q$. Conjecture: If $a + b$ is a non-zero rational, then both a and b are rational. (Preliminary question: is this a known result I'm not aware of?) I believe I have found a partial proof of the above. Namely, I first proved that ab is rational for $n = 1, 2, 3$. For $n = 2$, $(a + b)^2 = a^2 + 2ab + b^2$, so $$ab = \frac{(a+b)^2-a^2-b^2}{2} \in \mathbb Q$$ For $n = 3$, $(a + b)^3 = a^3 + 3ab(a + b) + b^3$, so $$ab = \frac{(a+b)^3-a^3-b^3}{3(a+b)} \in \mathbb Q$$ As it turns out, an additional assumption that $ab \in \mathbb Q$ allows proving the conjecture. The question: how can I prove $ab \in \mathbb Q$ for $n > 3$? (or what numbers are a counterexample?) The details of the proof assuming $ab \in \mathbb Q$ follow. Consider the polynomial $(x - a)(x - b) = x^2 - (a + b)x + ab$. Note that its coefficients are rational. This means that $\Pi \in \mathbb Q[x]$, the minimal polynomial of a, is of degree at most 2. Hence, $\deg \Pi \in \{1, 2\}$. If $\deg \Pi = 1$, then a is rational, which was to be proven, so let's assume that $\deg \Pi = 2$ and hope for a contradiction. As the minimal polynomial is unique, $\Pi = (x - a)(x - b)$. Moreover, Π divides $x^n - p$, since the latter has a root at a. Hence, the roots of Π are a subset of the roots of $x^n - p$. For odd n, we have $\{a, b\} \subseteq \{a\}$, so $a = b$. For even n, we have $\{a, b\} \subseteq \{a, -a\}$. b can't be equal to $-a$, since roots of even degree are nonnegative (or imaginary, but in that case $a + b$ wouldn't be rational). Hence, $a = b$. In both cases, from the assumption $a + b \in \mathbb{Q} \setminus \{0\}$, we get $2a \in \mathbb{Q} \implies a \in \mathbb Q$ and therefore $\deg \Pi = 1$, which is a contradiction.

The crosshatch conjecture, on primes in (p,p^2)

If the first p^2 integers are laid out in a $p\times p$ square, every row and column will have at least one prime. Easily visualized as so: I recognize this should maybe be packaged as two conjectures, but hey, I like the aesthetics. Individually, we have: Given some prime p, there will always be at least one prime in $[kp+1,kp+p-1]$ for all $1 \leq k \leq p-1$. Given some prime p, there will always be at least one prime q in (p,p^2) such that $q \equiv k \pmod{p}$ for all $1 \leq k \leq p-1$. I'm asking if a) this is somehow wrong or someone finds a counterexample, and b) if either of these conjectures already exist.

A pre-successor hyperoperation: subplus

I wrote up these notes about a month ago and just found them. I could really use a second opinion or two. I notice there's a whole question about how my whole thesis is wrong, but that doesn't automatically mean it's without merit. That said, forgive my layman's take on everything. Addition is a special case of multiplication. That follows from the whole set theory interpretation where units are indistinct in addition, but have types in multiplication. By that logic, you could also argue that multiplication is a special case of exponentiation. After all, $(a^b)^c=a^{bc}$, and $a^b \cdot a^c = a^{b+c}$. So, it's interesting; if you ignore the base, if you're taking a power, you're multiplying, as in the first case; and if you're multiplying, you're adding, as in the second case. What about if you're adding? It'd be nice if it turned out to be a^{b+1}, but I don't see how that's easily compatible. Adding 1 seems to require $a^b \cdot a=a^b \cdot a^{a^0}=a^{b+1}$. And on the other side, what operation gives exponentiation? Tetration? Hmm. Maybe adding requires another level of implicit base below everything. Even if it doesn't "exist" in a useful sense, other than to paint a more complete logical framework, or to serve as an intermediary tool. Putting this into action, addition is still just exponentiation, just with one deeper level of implicit base. Asking what's below addition is meaningless unless we allow that addition is just a label we've applied to that level of abstraction. We'll appropriate the symbol $\oplus$ for this hypothetical operation, and let γ serve as an exponential base. From powers on down, the four operations we've got now, reframed as exponentiation, look like: $$ \begin{align} x\textrm{ ^ }y&\Rightarrow&& x^y \\ x\times y&\Rightarrow&& (\alpha^x)^y = \alpha^{xy} \\ x+y&\Rightarrow&& (\beta^{\alpha^x})^{\alpha^y} =\beta^{\alpha^x \cdot \alpha^y} =\beta^{\alpha^{x+y}} \\ x\oplus y&\Rightarrow&& (\gamma^{\beta^{\alpha^x}})^{\beta^{\alpha^y}} =\gamma^{\beta^{\alpha^x} \cdot \beta^{\alpha^y}} =\gamma^{\beta^{(\alpha^x + \alpha^y)}} =\gamma^{\beta^{\alpha^{x \oplus y}}} \end{align} $$ One actual effect of this is we can infer that $x \oplus y$ is arbitrarily close to $\max(x,y)$. This is using $x\oplus y := \log_\alpha (\alpha^x+\alpha^y)$, but there are other possible interpretations of the extrapolation above. Mine was just an illustrative guess. But if we go ahead with the implication, I'm tempted to assign a real base value for more detail. More specifically, if the base is e, it's very close to $\max(x,y)$; if the base is $-e$, it's very close to $-\min(x,y)$. Upon some reflection though, I think the correct choice of base is $\alpha=2$, because then if $x=y$, you get $x \oplus y = x+1=y+1$, the successor function, which is what one expects for this level of hyperoperation. I acknowledge it's unusual to have a binary successor operation, it being famously unary and all. However, rather than break it, I think we've arguably improved it. By the same token, it might be reasonable to replace all the undefined base variables above with 2s. Note we have $x \oplus 0=\log_2 (2^x+1)$. As with every binary operation, all else being equal, the closer the two operands are to each other, the more the value is maximized. As an aside, it is awfully easy to represent everything computationally as exponentiation (even if it is just wrapping operations up in logs and powers). Observe: xTimes[a_,b_]:=Log2[(2^a)^b] xTimes[3,5] -> 15 xPlus[a_,b_]:=Nest[Log2,(2^2^a)^2^b,2] xPlus[3,5] -> 8 xSucc[a_,b_]:=Nest[Log2,(2^2^2^a)^2^2^b,3] N@xSucc[-100,-50] -> -50. N@xSucc[-5,19] -> 19. xSucc[-5,-5] -> -4 xSucc[4,4] -> 5 FYI - the Nest function

$\mathsf{nest}(f,n,k):=f(f(\ldots f(f(n))\ldots \textrm{k times} \ldots))$ So generally, I'm looking for responses like: a) "interesting ideas, worth considering further", or b) "crackpot idea, go read a book". I did find a post alluding to a well-regarded professor that seems to have had a similar thought, although I'm still trying to get details on that.

2'nd Law of thermodynamics in a relativistic gas?

Question I'm trying to understand in the context of a gas if a particular boundary condition can be used be to be the source of the 2'nd law of thermodynamics: "Given an isolated system the entropy will increase or remain the same." Is the attempt correct? Background Entropy is a statement of the likelihood of a configuration. If that is reflected in the action as well I think I have a chance? I try to make use of the fact it is only in thermal equilibrium (maximum entropy) that collisions can be neglected. Usually, the Hamiltonian of a gas at thermal equilibrium does not include a collision term which would imply at a collision: $$ \underbrace{\cdot}_{A} \rightarrow \leftarrow \underbrace{\cdot}_{B}$$ $$ \underbrace{\cdot}_{B} \leftarrow \rightarrow \underbrace{\cdot}_{A}$$ They actually go through each other. My attempt Consider a relativistic gas (point) particles with a 2 particles A and B in a box and the only collide once. The line element of the $A$and B before a collision is given by $ds_i^2 $ where $i=A$ or $i=B$. Similarly, the action is given by: $$ S_i = - m_ic \int_P d s_i$$ Where P is the world line before the collision $s_A^\mu = s_B^\mu$ where s_i^μ is the four position vector. After the collision, we know the momentum p^μ is conserved: $$ p_A^\mu + p_B^\mu = {p'}_A^\mu + {p'}_B^\mu$$ where ${p'}_i^\mu$ denotes the momentum after the collision. Differentiating with respect to $\frac{d}{ds_i}$ and using $ \frac{d p^\mu_i}{ds_i} =0$ then: $$ \frac{d p_j^\mu}{ds_i} = \frac{d {p'}_A^\mu}{ds_i} + \frac{d {p'}_B^\mu}{ds_i}$$ with $j \neq i$ After the collision the action is given by: $$ S'_i = - m_i c \int_{P'} d s'_i$$ where P' is the world line after the collision and $d s'_i$ is defined by $\frac{dp'_i}{ds'_i} = 0$. Let us write ds_A in terms of ds'_A. We proceed with: $$ \frac{d {p}_A^\mu}{ds_i} + \frac{d {p}_B^\mu}{ds_i} = \frac{d {p'}_j^\mu}{ds_i}$$ Using the chain rule: $$ \frac{d {p}_A^\mu}{ds_i} + \frac{d {p}_B^\mu}{ds_i} = \frac{d {p'}_j^\mu}{ds'_j} \frac{d s'_j}{ds_i} = \frac{\frac{d {p'}_j^\mu}{ds'_j}}{(\frac{d s'_j}{ds_i})^{-1}}$$ And as the L.H.S above is finite: $$\frac{d {p'}_j^\mu}{ds'_j} \to 0 \implies (\frac{d s'_j}{ds_i})^{-1} \to 0$$ Using L' Hopital Rule: $$ \frac{d {p'}_j^\mu}{ds_i} =\frac{d {p}_A^\mu}{ds_i} + \frac{d {p}_B^\mu}{ds_i} = \frac{\frac{d^2 {p'}_j^\mu}{{ds'_j}^2}}{\frac{d}{ds'_j}(\frac{d s'_j}{ds_i})^{-1}}$$ Or: $$\frac{d}{ds'_j}(\frac{d s'_j}{ds_i})^{-1} \frac{d {p'}_j^\mu}{ds_i} = \frac{d^2 {p'}_j^\mu}{{ds'_j}^2}$$ The above should be solvable as we have 2 boundary conditions (conservation of momentum and $s_i = s_j$). Hence: $$ {ds_i} = {d s'_j} \int \frac{d^2 {p'}_j^\mu}{{ds'_j}^2} (\frac{d {p'}_j^\mu}{ds_i})^{-1} {ds'_j}$$ Hence, the action of particle i is: $$ S_i = - m_ic \int_P {d s'_j} \Big (\int \frac{d^2 {p'}_j^\mu}{{ds'_j}^2} (\frac{d {p'}_j^\mu}{ds_i})^{-1} {ds'_j} \Big) - m_i c \int_{P'} d s'_i$$ One can take sum over i to find the net action. Heuristically? Since, the action depends on where the gas collides. It is possible to use this as a source for the second law in the limit of an infinite collisions?

Conjecture: All x^2+1 primes for $x>90$ can be represented as the sum of five x^2+1 primes.

For all $x>90$, I assert that any x^2+1 prime may be written as the sum of five smaller x^2+1 primes. In fact, above that bound, I think a stronger conjecture holds where one of said primes can always be 5. e.g. $$\begin{array}\\ 26^2+1&=677\\ &=401+197+37+37+5 \\ &=(20^2+1)+(14^2+1)+2(6^2+1)+(2^2+1) \end{array}$$ The only exceptions appear to be $x\in\{1,2,16,20,90\}$. The primes need not be distinct, although it seems that there is always at least one such representation for $x>170$. All statements above have been confirmed up to at least 10^6 with an apparent strong trend toward increasing numbers of representations. Below is a plot of the number of different representations for each x^2+1 prime, found by a brute force check using any five x^2+1 primes up through $1060^2+1=1123601$ (the 117th Landau prime). As expected, it only begins tapering off around that bound, and if I hadn't stopped there, I'd expect both minima and maxima to continue to rise. As an informal observation, it also seemed that the largest prime representable was gradually approaching $5(x^2+1)$. I'm interested in insight on the conjecture and/or confirmation/counterexamples. I am also curious whether this is related to (or even follows from) Lagrange's four-square theorem.

A conjecture about a smothness concerning consecutive primes

This is a conjecture inspired by the relative but piecewise smoothness of the sequence https://oeis.org/A068901/graph?png=1, about the least number a_n, such that $n\mid p_n+a_n$, where p_n is the n-th prime. Conjecture: $n\mid p_n+a \wedge 0≤a<n \Rightarrow \exists b\in\mathbb Z: n+1\mid p_{n+1}+b$, where $|a-b|<2\cdot\sqrt n$. Are there counter-examples, or can the conjecture be proved? Tested for all primes $p_n<100,000,000$. The conjecture badly describe the real smothness. Making some more experiments lead me to comment my question with an other conjecture: As above, given $\varepsilon>0$ there exist N such that $n>N \Rightarrow |a-b|<\varepsilon\sqrt n$.

Greatest common divisor of consecutive square free numbers

I guess that every prime number occurs as the greatest common divisor of two consecutive square free numbers, which I don't expect a proof of. But I've done some experiments indicating that: If m, n are consecutive square free numbers then $\gcd(m, n)$ is not composite. Is that true and can it be proved?

Prove or Disprove the Conjecture on Cousin Primes

Here is the problem in a nutshell - Ethers or Ether of n, $\mathbf{\eth(n)}$: Ethers of any number n is the set of all the values of every possible permutations of its digits. Illustration Ethers of 123, $\eth(123)$= $123, 132, 213, 231, 312$ and 321. Similarly it follows that $\eth(123)=\eth(132)=\eth(213)=\eth(231)=\eth(312)=\eth(321)$ Magnitude of Ether n, denoted by $|\eth(n)|$ is the total count of Prime Numbers we obtain by considering all of its Ethers individually. Illustration $|\eth(38)|=\mid\eth(83)|=1$, $|\eth(67)|=1$, $|\eth(251)|=2$, $|\eth(157)|=3$, $|\eth(973)|=4$, $|\eth(2183)|=6$, $|\eth(1379)|=7$, $|\eth(7309)|=9$, $|\eth(5917)|=10$, $|\eth(1237)|=11$ and so on... Zeroes of Ether Any natural number n such that $| \eth(n)|= 0$ is termed as zeroes of Ether, and if such n can be explained, trivially, then it's termed as Trivial Zeroes of Ether. Trivial Zeroes of Ether are classified as follows 1.) All the multiples of 3, $| \eth(3m)| = 0$, $m \in{W}$ 2.) The number having any of these digits $(0, 2, 4, 5, 6, 8)$ in any combinations. 3.) Any number (>11) entirely made up of only a single digit (>1). 4.) All the numbers of form $k \cdot 10^\alpha$, $\mathit{| \eth(k\cdot 10^\alpha)| =0, \, 0 \leq k \leq 9, \, \alpha\in{W}}$ CONJECTURE 1 If $P_{n+1} - P_n =2$ then there always exists k such that $| \eth(k)| = 0$ for $P_n < k < P_{n+1}$. CONJECTURE 2 If $P_{n+1} - P_n = 4$ then there exists minimum one k such that $| \eth(k)| \geq 1$ for $P_n < k < P_{n+1}$ where all of its Exceptions are Trivial Zeroes of Ether. It's just a segment from my original post On The Distribution of Prime Numbers I tried my best to handle this Conjecture 2 but couldn't get anywhere. I thought the representation of Primes in base 10 would incinerate this problem but no progress was made. Any progress will be highly appreciated. Remark \eth symbol is being utilitized for the new notions of digit permutations. Edit: Rephrased the Conjecture for better clarification.

Do all elements of $[n+1,2n]$ have strictly higher gpf than elements of $[1,n]$ when sorted by gpf?

For any $n\in\mathbb N$, let $A=\{x\in\mathbb N \mid 1 \leq x \leq n\}$ and $B=\{x\in\mathbb N \mid n+1 \leq x \leq 2n\}$. Order the sets by greatest prime factor of each element, ascending. Let A_1 be the element in A with the smallest gpf and A_n be the largest, and likewise for B. Conjecture: $\mathrm{gpf}(A_k)<\mathrm{gpf}(B_k)$ for all $1 \leq k \leq n$. e.g. Let $n=5$, and we have: $$ \begin{array}{|||||||} \hline A_k&\mathrm{gpf}(A_k)&\mathrm{gpf}(B_k)&B_k\\ \hline 1&1&2&8=2^3\\ \hline 2&2&3&6=2\cdot 3\\ \hline 4&2&3&9=3^2\\ \hline 3&3&5&10=2\cdot 5\\ \hline 5&5&7&7 \\ \hline \end{array} $$ where $\mathrm{gpf}(B_k)$ is strictly greater than $\mathrm{gpf}(A_k)$. I confirmed this empirically for $n<3000$. Informally, it looked like the trends strongly suggest it won't fail at any point. If this is a known result or conjecture, please share. Otherwise, I'm looking for counterexamples or any advice on how a proof could be approached$-$or a reason why a proof is likely to be difficult or impossible, as seems more typical with this stuff. Quicky data tables for $n<70$ are here.

A conjecture in number theory with twin primes

It's a conjecture found with the help of Wolfram Alpha : Let p_i be the first primes and $n>5$ with n an odd natural number numbers we are interested by the quantity : $$A=(1+p_1\times p_2(1+p_3\times p_4(1+p_5\times p_6(\cdots(1+p_n\times p_{n+1})^{\frac{1}{2}})\cdots)$$ Or $$A=(1+2\times 3(1+5\times 7(1+11\times 13(\cdots(1+p_n\times p_{n+1})^{\frac{1}{2}})\cdots)$$ Where p_n and p_{n+1} are twin primes numbers Example $$(1+2\times3(1+5\times7(1+11\times13(1+17\times19(1+23\times29(1+31\times37(1+41\times43)^{\frac{1}{2}})))))=311677481085187=7×43×433×2391393439$$ Conjecture 1 The last digit of A is seven . Conjecture 2 If A is not a prime number then A is divisible by 7. I try to work with divisibility rule for small numbers but it becomes insane with big numbers . I'm a very beginners in number theory so if you could use elementary tools it will be cool . Thanks a lot for your time and patience .

The Rook Conjecture: arrangement of p primes being distinct $\pmod{p}$ through p^2

For any prime p, divide $[1,p^2]$ into p equal intervals of length p, so that the first interval is $[1,p]$, the next $[p+1,2p]$, and so on. It is definitely unproven but seems likely that there will always be a prime in every one of these intervals. It is even probably true when you substitute any natural n in place of the prime p above. I've noticed a stricter condition that seems to hold. If you divide p^2 as described above, not only will there be a prime in every interval of length p, but there will always be at least one way to select those primes such that no value is repeated $\bmod{p}$. A good name for this might be the Rook Conjecture, as this is equivalent to saying that if you number the squares of a $p\times p$ sized chessboard, there is always at least one way to place p rooks on prime-numbered squares yet have no rooks share a rank or file. Examples $p=3,\qquad S=\{3,5,7\}\equiv\{0,2,1\} \pmod{3}$ $p=5,\qquad S=\{5,7,11,19,23\}\equiv\{0,2,1,4,3\} \pmod{5}$ etc. I've verified this for $p\leq 1000$. As usual, I am curious whether this is a known result and/or where to look for related work, and of course any counterexamples should they exist. I'm also curious whether this result seems to others to be surprising, or expected; I'm having a hard time deciding the answer for myself.

proof of prime in every interval (p^2,p^2+p)

Overview We'll introduce a sort of little hack called the missing modulo conjecture which can identify an integer's previous prime. We then show that this may not be perfectly reliable on account of how it interacts with all prime squares. In fact, we show that we would need a prime in every $(p^2,p(p+1))$ to be safe: we'd be forced to use them. Flip that around, though, and it means that proving the MMC incidentally guarantees us that prime existence (which we do still need). So we prove it, and since we know it works, it follows that those primes must exist after all. The missing modulo conjecture (MMC) The gist here is that you can take any integer, look at the results you get from taking that integer mod every smaller integer, and determine the nearest prime by noting which small factors could not be generated. For a given $n\in\mathbb N$, let a be the smallest nonnegative integer such that $n \not\equiv a \pmod {m}$, where m can take any value in the interval $[2,n/2]$. I assert that $n-a$ will always be the nearest prime $\leq n$. (See this question for more details.) Prime squares While the MMC mechanism most likely works perfectly, there's one big obstacle preventing its use in a proof. Let p be any prime. Then take $p(p+1) \not\equiv p \pmod{m}$ for $m\in \left[2,\frac{p(p+1)}{2}\right]$. This is the same operation as before aside from fixing p; it erroneously fails to return a factor of p, which is problematic because the typical range of p in these cases could conceivably overlap or interfere with a, and here, p does not point to a previous prime, meaning our a values could also be suspect. When $n=p(p+1)$, either there exists an $a<p$ and life is good, or we must default to $a=p$, since by definition we cannot have $a>p$ for the same n. If $a=p$, then since $n-a=p(p+1)-p=p^2 \not\in\mathbb P$, MMC would fail. For MMC to hold, we must always have our $a<p$. However, this requires $n-a=p(p+1)-a$ be prime. And since $a<p$, this prime would need to be found within $\left(p^2,p(p+1)\right)$. Given this conflict arises for every prime p, if we want the MMC to bear out, we would need a prime to be located in every similar prime square interval. Conversely, if MMC were independently found to always hold, the existence of these primes would necessarily follow. Solution: the MMC proof Let there be some prime gap $q'<\ldots<q$, with $c=q-q'-1$ being the number of composite values in (q',q). We're going to show that MMC works without issue in this instance, and by extension, everywhere else. The lowest missing mod value a on a prime n is always 0, and increments by 1 with each higher n until resetting to 0 at the next higher prime. At $q-1$, we'll be up to $a=c$; this requires we establish that no values $0 \leq v < a$ are possible, where v would be a hypothetical smaller missing mod result that we can't necessarily trust, like the prime square above. $v<a$ iff $q-1 \not\equiv v \pmod {m\in[2,\frac{q-1}{2}]}$. In other words, we're making sure that any v that exists is congruent to every last one of the c possible lower values than a, or more precisely, making sure it would have had to be congruent$-$really, we're ruling out possibilities: if none of those values are missing from the results of our mods, then no v using them could exist. To check that, we establish that $q-k\equiv [0,a-k] \pmod {m}$, meaning that for each $k\leq c$, we want to map it to one of several 0s we're about to find, at least one on each composite in the gap. The lower bound of our range means that any starting-at-0 mod value in the range $[k+1,(q-k)/2]$ won't cycle around to 0 until at least reaching q, so k will be removed from the pool of could-have-been v values. The best part is that because of the huge permissible range, you can simply rely on the greatest proper divisor of $q-k$ to qualify with no actual check or calculation required. Repeat this until all choices for v have been confirmed as observed, and therefore excluded. We'll have demonstrated that there cannot be a $v<a$, not even a bogus one like the prime square. With that addressed, there is no reason the same process cannot be implicitly applied to all prime gaps, which would prove MMC. And that in turn would prove there's always at least one prime in $\left(p^2,p(p+1)\right)$. (example) Consider the prime gap $(13,17)$. Identify three appropriate k_i such that $2\leq \gcd(k_1,16) \leq 8\qquad\qquad 3\leq\gcd(k_2,15) \leq 7\qquad \qquad 4\leq \gcd(k_3,14) \leq 7.$ We can go ahead and use $k_{1,2,3}=\{8,5,7\}$, the greatest proper divisors. These divisors correspond to mod values m which would yield 0, as they divide in cleanly: now, we know where some zeros are. Again, we're not changing anything; we're simply confirming things. Also, now we know that these are the

mod values which are possible to receive within our parameters: $ 14 \mapsto \{0,2,4\} \\ 15 \mapsto \{0,1,3\} \\ 16 \mapsto \{0,1,2,4\} $ Note the conspicuous absences of $\{1,2,3\}$, respectively. This is because those are the values a takes when given each n. And note we have accomplished our goal of confirming the impossibility of 0 for 14, $\{0,1\}$ for 15, and $\{0,1,2\}$ for 16 as potential values for v. Collectively they comprise all values lower than our own $a=\{1,2,3\}$, meaning MMC definitely works for this gap interval. Remember, this is only to illustrate the process, and because finding the divisors is guaranteed, the proof can be automatically applied to all gaps without any further work. I'm looking forward to having someone confirm or point me at the mistake. Much thanks for either. Further updates/improvements to come.

Erdős-Strauss Conjecture: Is there a simpler way to solve?

I'm a huge fan of conjectures, and I'm fascinated by this new one. The Erdős-Strauss conjecture is that $\frac{4}{n} = \frac{1}{a} + \frac{1}{b} + \frac{1}{c}$, where n is greater than or equal to 2 and is a natural number. Or, $\frac{4}{n}$, where n is greater or equal to two and is a natural number, can be written as the sum of three unit fractions. I know that I can eliminate all even numbers, because $\frac{4}{n}$ where n is even can be written as $\frac{1}{0.5n} + \frac{1}{n} + \frac{1}{n} = \frac{2}{n} + \frac{1}{n} + \frac{1}{n} = \frac{4}{n}$. The way I test the odd numbers is I subtract the nearest unit fraction less than $\frac{4}{n}$ and see if the difference can be written as the sum of two unit fractions. But as n keeps getting higher, my strategy doesn't work for long. So, my question is, what's a better strategy?

A Weak Schönflies Theorem in $\mathbb{R^n}$?

I was reading about the classical topological result of Schönflies that Jordan curve in a plane can be extended homeomorphically onto the whole plane. The well-known counterexample of Alexander's horned sphere tells us that the Schönflies' theorem does not extend into higher dimensions, but can we have a weaker version? Any homeomorphism of the sphere $\mathbb{S^{n-1}}$ onto a simple $(n-1)$-dimensional polygonal surface of $\mathbb{R^n}$ can be extended to a homeomorphism from $\mathbb{R^n}$ onto $\mathbb{R^n}$. EDIT: J. W. Alexander showed in 1920 that any simple $(n-1)$-dimensional polyhedral (polygonal surface) in $\mathbb{R^3}$ can be extended to a homeomorphism from $\mathbb{R^3}$ onto $\mathbb{R^3}$. The general result was proved in 1958 by B. Mazur in his PhD thesis.

The Generalized Bergström’s inequality

Prove the Generalized Bergström’s inequality For all $x_1,x_2,\ldots,x_n>0$ and $r \geq \frac{1}{n}$, it holds that $$\sum_{i=1}^n\frac{x_i}{\sqrt[nr]{x_i^{nr}+(n^{nr}-1)\prod \limits_{j=1}^nx^r_j}} \ge 1.$$ This is a slightly modified version of my earlier question here (which corresponds to the case $r=1$). The case $n=3$ and $r=\frac{2}{3}$ can be reduced to the inequality problem of IMO 2001 (Problem 2).

How do I solve the Continued Fraction $[1,x,x^2,x^3,\ldots]$

My function $M(x)$ is defined as $$M(x)=1+\cfrac{x^0}{1+\cfrac{x^1}{1+\cfrac{x^2}{1+\cfrac{x^3}{1+\cfrac{x^4}{1+\cfrac{x^5}{1+\cfrac{x^{6}}{1+\cfrac{x^{7}}{1+\cfrac{x^{8}}{1+\cfrac{x^9}{1+\cfrac{x^{10}}{1+\ddots}}}}}}}}}}$$ I understand the Rogers-Ramanujan Continued Fraction $R(a,q)$ is very similar but it is slightly different. I would like to know what $M(2)$ is, but I learned that any value $|q|>1$ starts to split and become two different values. What are the decimal approximations of $M(2)$ for both n=even and n=odd and what are their exact values? This is my first question on this site so if it's janky or similar to an answer already I'm sorry.

Conjecture about a continued fraction

Conjecture: $$\large 2^{n-1}+\frac{1}{2+\cfrac{1}{2^{n}-1+\cfrac{1}{2+\cfrac{1}{2^{n}-1+\cfrac{1}{2+\ddots}}}}}=\frac{1+\sqrt{3a_n}}{2}\tag*{[1]}$$ such that $a_n=4a_{n-1}+1$ and $a_0=0$.$\quad(n\geqslant 1)$ Ex. If $n=1$, then $a_n=4a_0+1=4\times 0 + 1 = 1$. $$\therefore 1+\frac{1}{2+\cfrac{1}{1+\cfrac{1}{2+\cfrac{1}{1+\cfrac{1}{2+\ddots}}}}}=\frac{1+\sqrt{3}}{2}\tag*{[2]}$$ This can be proven using the formula $x=a+\dfrac{1}{b+\dfrac{1}{x}}=a+\dfrac{1}{b+\dfrac{1}{a+\dfrac{1}{b+\dfrac{1}{a+\ddots}}}}$ Solving for x results in a quadratic equation for which $x=\dfrac12\left\{a+\sqrt{a\left(a+\dfrac4b\right)}\right\}$. Substituting $a=1$ and $b=2$ yields $[2]$ as required. Problem is, I am unsure on how to (dis)prove this conjecture given the recursive sequence involved. How do I appropriately go about this? Any suggestions or counter-examples? Thanks :)

Conjectured summation inequality

I was playing around with numbers and noticed that the following series is quite close to $\sqrt 2$... but not quite. So I have conjectured that $\sqrt 2$ is arguably the closest highest bound; $$1+\frac 12\left(1-\frac{1}{2^2}\right)+\frac{1\cdot 3}{2\cdot 4^2}\left(\frac{1}{2}-\frac{1}{3^2}\right)+\frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6^3}\left(\frac{1}{3}-\frac{1}{4^2}\right)+\cdots < \sqrt{2}$$ Can this be proven? Is there a closed form of the infinite series? I... have no idea how to tackle this problem. I've never seen anything like this and have just made it up because I was bored in physics class, but after some iterations, methinks this series is convergent. Are there any series that look like this, particularly for $\sqrt 2$, that may serve a good use of application to measuring the truth of this conjecture? Thanks. :)

Is this elementary-number-theoretic conjecture already mentioned somewhere or it is entirely new?

While I was doing some research in elementary number theory I discovered some regularities that seem to be very promising. First, function d can be defined as $d(n)=d(\prod_{i=1}^{k(n)} p_i^{r_i})=\sum_{i=1}^{k(n)}r_i$ where $n=\prod_{i=1}^{k(n)} p_i^{r_i}$ is unique prime factorization of n and it can be said that natural number $n>1$ is of degree w if and only if $d(n)=w$. So, for example, prime numbers are natural numbers of first degree. The conjecture I would like to propose is the following: Every prime number ≥7 is the sum of a prime number and number of second degree. As noted in the comments, the conjecture can be rephrased very simply as: Every prime number $p\geq 7$ can be written as $p=qr+s$ where q,r,s are primes.

Minimal counterexample to $\frac{p - 1}{p^2}$-conjecture

There existed once a “folklore” conjecture that stated: Suppose p is a prime. Then any finite group G with $> (1 - \frac{p-1}{p^2})|G|$ elements of order p has exponent p This conjecture was disproved by G.E.Wall in 1965, who constructed a group of exponent 25, where all elements of order 25 lie in the subgroup of index 25. My question is: What is the minimal possible size of a counterexample to this conjecture? I am interested in it because I collect disproven conjectures with large minimal counterexamples Note, that p in this counterexample has to be 5 of greater, as the conjecture was proven to be true for $p = 2$ and $p = 3$ by Thomas Laffey in 1976.

Formula for Feigenbaum’s constant?

I have conjectured a formula to calculate the Feigenbaum constant $\delta \approx 4.66920$. $\delta\stackrel{?}{=}$ $$4+\cfrac{1\times 2 -1}{1+\cfrac{2\times 3 -1}{2^2+\cfrac{3\times 4 -1}{1+\cfrac{4\times 5 -1}{3^2+\cfrac{5\times 6 -1}{1+\ddots}}}}}$$ which after several iterations is ≈ 4.66919 (I believe). This discovery, whether exact or approximate, was completely accidental. Can this be numerically verified? Thanks.

Prove that $\sum_{k=2}^{n}\{\sqrt{a_{k-1}}+\sqrt{a_{k}}\}^{-1}=\frac{n-1}{\sqrt{a_{1}}+\sqrt{a_{n}}}$

If $a_{1}, a_{2}, a_{3}, \dots, a_{n}$ are consecutive terms of an arithmetic progression (None of which are 0) , prove that $\sum_{k=2}^{n}\{\sqrt{a_{k-1}}+\sqrt{a_{k}}\}^{-1}=\frac{n-1}{\sqrt{a_{1}}+\sqrt{a_{n}}}$ I started out doing this problem by approaching it using mathematical induction. If my calculations are right, it must be proved through induction that $\frac{k-1}{\sqrt a_{1}+\sqrt{a_{n}}}+\frac{1}{\sqrt{a_{k}}+\sqrt{a_{k-1}}}=\frac{k}{\sqrt{a_{1}}+\sqrt{a_{k-1}}}$ Trying to simplify this gives me a very long expression. I assume that we have to use the fact that the terms are in AP. Any help is appreciated.

On conjectured continued fractions and e

Playing around with numbers, I conjectured three incredibly interesting things: $$9+\cfrac{1}{18+0\times 12\cfrac{1}{18+1\times 12+\cfrac{1}{18+2\times 12+\cfrac{1}{18+3\times 12+\ddots}}}}=\frac{4e^{1/3}-2}{e^{1/3}-1}$$ $$6+\cfrac{1}{9+0\times 6+\cfrac{1}{9+1\times 6+\cfrac{1}{9+2\times 6+\cfrac{1}{9+3\times 6+\ddots}}}}=\frac{4e^{2/3}-2}{e^{2/3}-1}$$ $$5+\cfrac{1}{6+0\times 4+\cfrac{1}{6+1\times 4+\cfrac{1}{6+2\times 4+\cfrac{1}{6+3\times 4+\ddots}}}}=\frac{4e-2}{e-1}$$ So, what in God's name is going on behind the scenes? Why does this seem to be true, why does it involve e, so many questions! All I did was play around on a calculator with some continued fractions, went to Wolfram Alpha and asked for the result to be written in terms of e and then I noticed some patterns. But what is really going on? Well, apart from a bit of luck, I have no idea. Any ideas? Thanks. Edit: This question may be of help, as it reveals general continued fractions regarding the hyperbolic tangent, which to those who don't know, is a function with respect to some value α defined as $\tanh(\alpha):=\frac{e^{2\alpha}-1}{e^{2\alpha}+1}.$

On expressing $\frac{\pi^n}{4\cdot 3^{n-1}}$ as a continued fraction.

It is a celebrated equation that $$\frac{\pi}{4}=\cfrac{1}{1+\cfrac{1^2}{3+\cfrac{2^2}{5+\cfrac{3^2}{7+\ddots}}}}$$ However, there are two other conjectured equations that I found which, if true (they seem to be), might reveal a pattern. $$\frac{\pi^2}{12}=\cfrac{1}{1+\cfrac{1^4}{3+\cfrac{2^4}{5+\cfrac{3^4}{7+\ddots}}}}$$ $$\frac{\pi^3}{36}=\cfrac{1}{1+\cfrac{1^6}{3+\cfrac{2^6}{5+\cfrac{3^6}{7+\ddots}}}}$$ Conjectured General Formula: For natural $n\geqslant 1$, $$\frac{\pi^n}{4\cdot 3^{n-1}}=\cfrac{1}{1+\cfrac{1^{2n}}{3+\cfrac{2^{2n}}{5+\cfrac{3^{2n}}{7+\ddots}}}}$$ Can these be numerically verified? I have not the skill to by-hand prove/disprove these, and have only been using Wolfram Alpha to arrive at these conjectures. It would also be much appreciated if one could suggest a program I could install in order to evaluate these continued fractions independently, as well as the code required. Will PARI/GP suffice? Thanks.

Interesting patterns related to the sums of the remainders of integers

Let us define, $$r(b)=\sum_{k=1}^{\lfloor \frac{b-1}{2} \rfloor} (b \bmod{k})$$ After reading the posts Surprising fact about a certain number-theoretic function and Do primes have special sums... I decided to play around with the $r(b)$ function and after performing some computations using PARI/GP, I found some very interesting patterns. $r(a^n)-r(a^n-1)=0$ when $a\in {2, 3}$ for any $n\in \Bbb{N}$. (Proved by user Haran in the first post) For fixed a and any $n\in \Bbb{N}$, $r(a^n)-r(a^n-1)$ is either always positive or always negative when a is not of the form $2p$ or $3q$ where p,q are prime and $p\gt 3, q\gt 7$. For fixed a, $r(a^n)-r(a^n-1)$ is initially postive and then becomes negative as $n\in \Bbb{N}$ increases when a is the form of $2p$ or $3q$ where p,q are prime and $p\gt 3, q\gt 7$. If $a \notin \{2p, 3p\}$ is prime or semiprime then $r(a^n)-r(a^n-1)$ is positive for all $n\in \Bbb{N}$. (edit) What is the reason for these weird characteristics or $r(a^n)-r(a^n-1)$? I would really appreciate if someone could prove/disprove any of the last 3 observations. Here is some of the initial data from where I made my observations. The first column gives the a values, the second gives the n values, and the third gives the corresponding values of $r(a^n)-r(a^n-1)$. 1 1 0 1 2 0 1 3 0 1 4 0 1 5 0 2 1 0 2 2 0 2 3 0 2 4 0 2 5 0 3 1 0 3 2 0 3 3 0 3 4 0 3 5 0 4 1 0 4 2 0 4 3 0 4 4 0 4 5 0 5 1 1 5 2 6 5 3 31 5 4 156 5 5 781 6 1 -1 6 2 -20 6 3 -169 6 4 -1160 6 5 -7381 7 1 2 7 2 16 7 3 114 7 4 800 7 5 5602 8 1 0 8 2 0 8 3 0 8 4 0 8 5 0 9 1 0 9 2 0 9 3 0 9 4 0 9 5 0 10 1 1 10 2 -18 10 3 -341 10 4 -4212 10 5 -46079 11 1 4 11 2 48 11 3 532 11 4 5856 11 5 64420 12 1 -5 12 2 -116 12 3 -1625 12 4 -20360 12 5 -247445 13 1 5 13 2 70 13 3 915 13 4 11900 13 5 154705 14 1 3 14 2 -8 14 3 -513 14 4 -10000 14 5 -159657 15 1 -2 15 2 -66 15 3 -1178 15 4 -18564 15 5 -282722 16 1 0 16 2 0 16 3 0 16 4 0 16 5 0 17 1 7 17 2 126 17 3 2149 17 4 36540 17 5 621187 18 1 -4 18 2 -200 18 3 -4732 18 4 -95120 18 5 -1800964 19 1 8 19 2 160 19 3 3048 19 4 57920 19 5 1100488 20 1 -3 20 2 -162 20 3 -3813 20 4 -79092 20 5 -1595583 21 1 -1 21 2 -80 21 3 -2109 21 4 -47200 21 5 -1011161 22 1 7 22 2 36 22 3 -665 22 4 -30744 22 5 -853565 23 1 10 23 2 240 23 3 5530 23 4 127200 23 5 2925610 24 1 -13 24 2 -500 24 3 -13273 24 4 -327560 24 5 -7929493 25 1 6 25 2 156 25 3 3906 25 4 97656 25 5 2441406 26 1 9 26 2 70 26 3 -549 26 4 -45220 26 5 -1577991 27 1 0 27 2 0 27 3 0 27 4 0 27 5 0 28 1 -1 28 2 -200 28 3 -6897 28 4 -202000 28 5 -5716841 29 1 13 29 2 390 29 3 11323 29 4 328380 29 5 9523033 30 1 -13 30 2 -1022 30 3 -39601 30 4 -1309532 30 5 -40972393 31 1 14 31 2 448 31 3 13902 31 4 430976 31 5 13360270 32 1 0 32 2 0 32 3 0 32 4 0 32 5 0 33 1 1 33 2 -96 33 3 -4655 33 4 -169824 33 5 -5781695

For fixed hypotenuse, can the number of primitive Pythagorean triples exceed the number of non-primitive ones?

For the equation, $$a^2+b^2=c^2$$ if c is fixed and the number of natural solutions for a, b is greater than 1, then can the number of primitive solutions (solutions in which a, b, c are coprime) exceed the number of non-primitive ones? After testing a large number of cases I believe that the number of non-primitive solutions will always exceed the number of primitive ones although I have no proof for this. If false, what is the smallest counter-example for c?

Interesting property related to the sums of the remainders of integers

Cross-posted on Math Overflow too Let us define, $$r(b)=\sum_{k=1}^{\lfloor \frac{b-1}{2} \rfloor} (b \bmod{k})$$ After playing around with the $r(b)$ function for sometime I noticed that $r(b)$ appreared to be more even than odd. So to see the difference between the number of even and odd terms of $r(b)$, I defined a function, $$z(x)=\sum_{n=1}^x(-1)^{r(n)}$$ When user Peter ran a program for computing values of $z(x)$ in PARI, I observed that for $x\le 10^{10}$, $z(x)\gt 0$. This suggests that there are always more even terms of $r(n)$ than odd terms for any x. This leads to my two questions: Is $z(x)$ always positive? If so, then how do we prove this? Is $|z(x)|$ bounded by some maximum value? If so, then what is this maximum value? Till now the maximum value of $|z(x)|$ found was 49 for $x = 5424027859$. I find it odd that $|z(x)|$ goes to these large values and then returns back to small values as small as 1. Edit: With the help of user Vepir I was able to plot $z(x)$ and noticed that the function has a sinusoidal-fractal-like appearance and it seems to grow without bounds, although very very slowly. Is there any reason for this sinusoidal and fractal nature?

For any $k \gt 3$, if $n!+k$ is a perfect power then does there exist any $n\gt k$?

A while ago, I asked a similar question For any $k \gt 1$, if $n!+k$ is a square then will $n \le k$ always be true? where users mathworker21 and WE Tutorial School proved that for non-square k, $n\le k$ is always true when $n!+k$ is sqaure. Recently I got the idea to check if the property is true for all perfect powers and using PARI, I observed that if, $$n!+k=a^b$$ where $n, k, a, b\in \Bbb{N}$, $k\gt 3$ and $b\ge 2$, then $n\le k$ is always true. In search for a counter-example, I covered a range of $k\le 2500$ and $n\le 10^4$ for each k and found none. So my question is, If true, can we prove/partially prove that $n\le k$ always holds? If false, then what is the smallest counter-example where $n\gt k$?

Pattern in Number of Conjugacy Classes of p-groups

I was playing around with the number of conjugacy classes of p-groups in GAP and made the following conjecture: If there is a group of order p^{2n} with k conjugacy classes then there is a group of order p^{2n+1} with $k+p-1$ conjugacy classes. The only exception is $p=2$, $n=2$, $k=7$. For example, there are groups of order 64 with $\{13,16,19,22,25,28,34,40,64\}$ many conjugacy classes so there are groups of order 128 with $\{14,17,20,23,26,29,35,41,65\}$ many conjugacy classes. Can someone prove this or find a counterexample? For reference, here is the data that I was using. [1] [2] [4] [5.8] [7.10,16] [11,14,17,20,32] [13,16,19,22,25,28,34,40,64] [14,17,20,23,26,29,32,35,38,41,44,50,56,65,68,80,128] [19,22,25,28,31,34,37,40,43,46,49,52,55,58,61,64,67,70,73,76,82,85,88,100,112,130,136,160,256] [1] [3] [9] [11,27] [17,33,81] [19,35,51,83,99,243] [41,57,73,89,105,121,153,249,297,729] [43,59,75,91,107,123,139,155,171,187,219,251,267,299,315,363,459,731,747,891,2187] [1] [5] [25] [29,125] [49,145,625] [53,149,245,629,725,3125] [73,169,265,361,649,745,841,1225,3145,3625,15625] [1] [7] [49] [55,343] [97,385,2401] [103,391,679,2407,2695,16807] n:=16; l:=[]; for i in [1..NrSmallGroups(n)] do G:=SmallGroup(n,i); if not \in(NrConjugacyClasses(G),l) then Add(l,NrConjugacyClasses(G)); Sort(l); fi; od; Print(l); One well-known pattern in the above data is a result of Hall that if $n=2k+e$ (with $e=0,1$) then $k=p^e+(p^2-1)(n+(p-1)t)$ for some $t\geq0$. This explains why the above lists jump by $(2-1)(2^2-1)=3$ when $p=2$, by $(3-1)(3^2-1)=16$ when $p=3$, by $(5-1)(5^2-1)=96$ when $p=5$, and by $(7-1)(7^2-1)=288$ when $p=7$.

Conjecture $\frac{a}{a^r+b^r}+\frac{b}{b^r+c^r}+\frac{c}{c^r+a^r}\geq \frac{a}{a^r+c^r}+\frac{c}{c^r+b^r}+\frac{b}{b^r+a^r}$

following this kind of inequality One of my old inequality (very sharp) I propose this because I don't see it on the forum : Let $a,b,c>0$ and $a+b+c=1$ with $r\in(\frac{1}{2},1)$ and $a\geq b \geq c$ then we have : $$\frac{a}{a^r+b^r}+\frac{b}{b^r+c^r}+\frac{c}{c^r+a^r}\geq \frac{a}{a^r+c^r}+\frac{c}{c^r+b^r}+\frac{b}{b^r+a^r}$$ First of all it's a conjecture where I don't find counter-examples . Secondly when $r\in(0,\frac{1}{2})$ the inequality is reversed .I use Pari-gp for that .Furthermore (if it's true) I think it's really not new so I add the tag reference request.We have an equality case when $r=0.5$ whenever $a,b,c>0$. So if you have idea to prove it or disprove it... Thanks a lot .

Expectation of arbitrary product of Brownian motions.

Let (B_t) be a standard Brownian motion, $n\in\mathbb{N}$ even and $t_1,\ldots,t_n\in\mathbb{N}$. I was wondering whether there is a general formula for $$\mathbb{E} \left[B(t_1)\cdots B(t_n)\right].$$ By successively applying the property of independent increments, it is straightforward to calculate this expression for some fixed $n\in\mathbb{N}$. Now my conjecture is the following. Let $\mathcal{P}_n$ be the set of partitions of $\{1,\ldots,n\}$ into two-element subsets. Then $$\mathbb{E} \left[B(t_1)\cdots B(t_n)\right] \stackrel{?}{=} \sum_{P\in\mathcal{P_n}} \prod_{\{i_1,i_2\}\in P} t_{i_1} \wedge t_{i_2}.$$ I confirmed this by hand for n up to 6 and tried to prove it by induction , but failed. I would be grateful for any advice on how to prove this or a known formula for $\mathbb{E} \left[B(t_1)\cdots B(t_n)\right].$ For illustration, this is the formula for $n=4$: There are three partitions of $\{1,2,3,4\}$, namely $\{\{1,2\},\{3,4\}\}$, $\{\{1,3\},\{2,4\}\}$ and $\{\{1,4\},\{2,3\}\}$. Their contributions to the sum are $t_2 t_4$, $t_3 t_4$ and $t_4 t_3$ respectively (assuming $t_1>t_2>t_3>t_4$), yielding the correct result $2t_3 t_4 + t_2 t_4$.

Is the last digit of $2^{2^{n-1}(2^n-1)}-1$ always 5 for $n >3$?

Is the last digit of $2^{2^{n-1}(2^n-1)}-1$ always 5 for $n >3$? I did modification to the Mersenne numbers (Even perfect numbers) foruma I put that formual to be the power of 2 have got : $2^{2^{n-1}(2^n-1)}-1$, Now for some values of $n >3$ that i have tried i have got the produced integer with last digit equal 5 like this example, Now to do more n or so large to conjecture that it is beyond of current tecknology , Really am interesting to prove that if it is true ?

Conjectured continued fraction formula for Catalan's constant

Yesterday I posted this conjecture, but then deleted it thinking it was false. Turns out Python doesn't define a^b as a^b, but rather as a**b. Conjecture: Denote by G Catalan's constant, then $$G=\cfrac{1}{1+\cfrac{1^4}{8+\cfrac{3^4}{16+\cfrac{5^4}{24+\cfrac{7^4}{32+\cfrac{9^4}{40+\ddots}}}}}}$$ Given the connection G has with the number 8 shown here, as well as this continued fraction reaching nearly the first five decimal places of G after around 200 iterations (vinculums), I am confident this is true. However, I do not know how to code a continued fraction on Python or Pari/GP (a friend of mine gave it a go, but also to no avail) up to an iteration n without having to write it out manually, which is really tedious. Here is some python code from a friend, coding this fraction up to 12 iterations to be ≈ 0.9151, reaching the first three decimal places of G. The only 'local' behaviour that I can say about continued fractions is that most of them are convergent, and that they all converge via oscillation at each iteration. But, more importantly, I'd like to know that if this be true, can it be shown from here that G is irrational (or even transcendental, if you are willing)? I am aware this is an unsolved problem, which was what inspired me to write G in another closed form. Any thoughts? Thank you in advance.

Attempt to get a characterization of even perfect numbers from an equation involving the Dedekind psi function

In this post we denote the Dedekind psi function as $\psi(n)$ for integers $n\geq 1$. This is an important arithmetic fuction in several subjects of mathematics. As reference I add the Wikipedia Dedekind psi function. An even perfect number is an even integer $n\geq 1$ satisfying that $\sigma(n)=2n$, where $\sigma(n)=\sum_{1\leq d\mid n}d$ is the sum of divisors function. Claim. Invoking Euclid-Euler theorem it is easy to prove that each even perfect number satisfies $$4\psi(n)^2-(12n+3)\psi(n)=-9n^2,\tag{1}$$ alternatively $$\psi(n)=\frac{12n+3+3\sqrt{1+8n}}{8}.\tag{2}$$ Question. I would like to know if it is possible to get a characterization for even perfect numbers from (1): what I evoke is if we can to prove that if an integer $n\geq 1$ satisfies (1) then n is an even perfect number. Many thanks. The case $n=1$ is easy. By contradiction also is easy to rule out/discard that n is a power of two and that n is odd. Thus the only discussion is what happens with numbers of the form $$n=2^{\alpha}m\tag{3}$$ where $\alpha\geq 1$ is integer and $(2,m)=1$ for integers $m>1$. Our case (3) leads to $$2^{\alpha+1}m\prod_{\substack{\text{primes }p\\p\mid m}}(p+1)^2-(2^{\alpha+2}m+1)\prod_{\substack{\text{primes }p\\p\mid m}}p(p+1)=2^{\alpha+1}m \prod_{\substack{\text{primes }p\\p\mid m}}p^2,\tag{4}$$ and if I was right from (4) on assumption that $m=p$ is a prime (that is we assume that the number of distinct primes dividing m is $\omega(m)=1$) I get that $p+1=\lambda 2^{\alpha+1}$ with $\lambda=1$ using the congruence $\prod_{\substack{\text{primes }p\\p\mid m}}(p+1)\equiv 0\text{ mod }2^{\alpha+1}$. Thus if my argument works I need to rule out/discard the case of integers m with more than 1 distinct primes factors in their prime factorization (I want to remove the case $\omega(m)>1$).

If $q^k n^2$ is an odd perfect number with special prime q, then $k \neq 1$ (MSE version)

Note that $\gcd(\sigma(q^k),\sigma(n^2))=i(q)=\gcd(n^2,\sigma(n^2))$ if and only if $\gcd(n,\sigma(n^2))=\gcd(n^2,\sigma(n^2))$. I have therefore undeleted this question, in view of this closely related MSE question: When does $\gcd(m,\sigma(m^2))$ equal $\gcd(m^2,\sigma(m^2))$? What are the exceptions?. (Cross-posting this question from MO, as I think it is about to be closed there, due to some reasons yet unknown to myself.) This question is directly related to this earlier one ("On odd perfect numbers and a GCD - Part II") in MSE. That question has all the details. Now, let $N = q^k n^2$ be an odd perfect number with special prime q satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Descartes, Frenicle, and subsequently Sorli conjectured that $k=1$ always holds. In the hyperlinked MSE question, we have the equation $$\gcd(\sigma(q^k),\sigma(n^2))=i(q)=\gcd(n^2,\sigma(n^2))$$ where $$i(q)=\frac{\sigma(n^2)}{q^k}=\frac{2n^2}{\sigma(q^k)}.$$ Assume to the contrary that $k=1$. By Brown (2016), it follows that $q < n$, whence it follows that $\sigma(q^k) = \sigma(q) = q + 1 < n$. But $i(q) = \gcd(\sigma(q^k),\sigma(n^2))$; in particular, this means that $$i(q) \mid \sigma(q^k) \implies \frac{2n^2}{\sigma(q^k)} = \frac{\sigma(n^2)}{q^k} \leq \sigma(q^k).$$ We know that $\sigma(q^k) < n$, so we have $$2n < \frac{2n^2}{\sigma(q^k)} = \frac{\sigma(n^2)}{q^k} \leq \sigma(q^k) < n,$$ resulting in a contradiction. We therefore conclude that $k \neq 1$.

Does the fraction of distinct substrings in prefixes of the Thue-Morse sequence of length 2^n tend to $73/96$?

Recall that the Thue-Morse sequence$^{[1]}$$\!^{[2]}$$\!^{[3]}$ is an infinite binary sequence that begins with $\,t_0 = 0,$ and whose each prefix p_n of length 2^n is immediately followed by its bitwise complement (i.e. obtained by flipping $0\to1$ and $1\to0$): $$ \begin{array}{c|cc}&t_0&t_1&t_2&t_3&t_4&t_5&t_6&t_7&\!\!\!\dots\\\hline p_0&0\\ p_1&0&\color{red}1\\ p_2&0&1&\color{red}1&\color{red}0\\ p_3&0&1&1&0&\color{red}1&\color{red}0&\color{red}0&\color{red}1\\ \cdots&\cdots\!\! \end{array} $$ We are interested in contiguous substrings of these prefixes. For a string $\mathcal{S}$ of length ℓ, the total number of its substrings, including the empty substring $\langle\unicode{x202f}\rangle$ and the string $\mathcal{S}$ itself, is

$(\ell^2+\ell+2)/2.$ Hence, the total number of substrings in p_n is $(4^n+2^n+2)/2.$ Clearly, not all of those substrings are distinct for $n>1$. For example, $p_2 = \langle0\,1\,1\,0\rangle$ has 11 substrings in total, but only 9 distinct substrings: $$ \begin{array}{|cc}&\langle\!\!\!&0&\color{#808080}1&\color{#b8b8b8}1&\color{#c8c8c8}0&\!\!\!\rangle\\\hline 1&\langle\!\!\!&&&&\!\!\!\rangle\\\hdashline 2&\langle\!\!\!&0&&&\!\!\!\rangle\\ &\langle\!\!\!&&&&\color{#c8c8c8}0&\!\!\!\rangle\\\hdashline 3&\langle\!\!\!&&\color{#808080}1&&&\!\!\!\rangle\\ &\langle\!\!\!&&&\color{#b8b8b8}1&&\!\!\!\rangle\\\hdashline 4&\langle\!\!\!&0&\color{#808080}1&&&\!\!\!\rangle\\ 5&\langle\!\!\!&&\color{#808080}1&\color{#b8b8b8}1&&\!\!\!\rangle\\ 6&\langle\!\!\!&&&\color{#b8b8b8}1&\color{#c8c8c8}0&\!\!\!\rangle\\ 7&\langle\!\!\!&0&\color{#808080}1&\color{#b8b8b8}1&&\!\!\!\rangle\\ 8&\langle\!\!\!&&\color{#808080}1&\color{#b8b8b8}1&\color{#c8c8c8}0&\!\!\!\rangle\\ 9&\langle\!\!\!&0&\color{#808080}1&\color{#b8b8b8}1&\color{#c8c8c8}0&\!\!\!\rangle \end{array} $$ Among these, $\langle0\rangle$ and $\langle1\rangle$ appear in p_2 twice, so the fraction of distinct substrings in p_2 is $\,\stackrel9{}\!\!\unicode{x2215}_{\!\unicode{x202f}11}\!.$ Can we find a simple general formula for $\mathscr D_n$, the number of distinct substrings in p_n? Let's try to compute a few terms: $$2,\,4,\,9,\,28,\,101,\,393,\,1561,\,6233,\,24921,\,99673,\,398681,\,1594713,\,6378841,\,\dots$$ These few terms can be computed by a brute-force approach, but using Coolwater's program from here we can compute hundreds of thousands more. It is not too difficult to discover that for $n>2$ all known terms match a simple formula: $$\mathscr D_n\stackrel{\color{#d0d0d0}?}=\frac{73\cdot4^n+704}{192}\color{#d0d0d0}{\,\,\text{for}\,\,n>2}\tag{$\diamond$}$$ Somewhat oddly, the three initial terms $\mathscr D_0=2,\,\mathscr D_1=4,$ and $\mathscr D_2=9$ do not match the general formula $(\diamond)$, which results in non-integer rational values for these indexes. I conjecture that the general formula $(\diamond)$ is valid for all $n>2$. $$\bbox[LemonChiffon]{\begin{array}{c} \\ \hspace{1in}\text{Could you suggest a way to prove this conjecture?}\hspace{1in}\\ \vphantom. \end{array}}$$ If the conjecture turns out to be true, then we have a remarkable corollary that for $n\to\infty$ the fraction of distinct substrings in the prefixes p_n tends to a quite surprising limit: $$\mathscr L=\lim_{n\to\infty}\frac{73\cdot4^n+704}{192}{\large/}\frac{4^n+2^n+2}2=\frac{73}{96}.\tag{$\small\spadesuit$}$$

Prove that $1=\sqrt{2\cdot \color{red}{-1} + \sqrt{2\cdot \color{red}2 + \sqrt{2\cdot \color{red}{9}+\sqrt{2\cdot\color{red}{20}+\cdot \cdots}}}}$

I was playing around with square roots and I noticed that the number 1 can be seemingly expressed as an infinite nested radical with an easy pattern. I then noticed that if this is true, this would mean that each nested radical inside is equal to the next odd number, respectively. I have tried to denote this using LaTeX but it did not display as I thought it might, though I hope you can understand what I am trying to concisely say. Conjecture: $$\begin{align}\color{green}1 &= \sqrt{2\cdot \color{red}{-1} + \color{green}{3}} \\ &= \sqrt{2\cdot \color{red}{-1} + \sqrt{2\cdot \color{red}2 + \color{green}{5}}} \\ &= \sqrt{2\cdot \color{red}{-1} + \sqrt{2\cdot \color{red}2 + \sqrt{2\cdot \color{red}{9}+\color{green}7}}}\\ &= \sqrt{2\cdot \color{red}{-1} + \sqrt{2\cdot \color{red}2 + \sqrt{2\cdot \color{red}{9}+\sqrt{2\cdot\color{red}{20}+\color{green}9}}}}\\ &= \sqrt{2\cdot \color{red}{-1} + \sqrt{2\cdot \color{red}2 + \sqrt{2\cdot \color{red}{9}+\sqrt{2\cdot\color{red}{20}+\sqrt{2\cdot \color{red}{35}+\cdots}}}}}\end{align}$$ $\color{red}{-1}+(4\cdot 0+3)=\color{red}{2}$ (radical $=\color{green}1$) $\color{red}2+(4\cdot 1+3)=\color{red}9$ (radical $=\color{green}3$) $\color{red}9+(4\cdot 2+3)=\color{red}{20}$ (radical $=\color{green}5$) $\color{red}{20}+(4\cdot 3+3)=\color{red}{35}$ (radical $=\color{green}7$) $\cdots = \cdots$ Can this be proven? If it is a result of a generalised identity for odd numbers $2n+1$ (for some n, this case being $n=0$), please let me know. Thanks. Edit: @TheSimpliFire kindly gave the recurrence relation: $1=2a_0+b_n$ where $b_n=\sqrt{2a_n+b_{n+1}}$ and $a_n+4n+3=a_{n+1}$ with $a_0=-1$ and $n>0$.

Conjecture on a functional equality and nested radical of Ramanujan :$3=\sqrt{1+f(2)\sqrt{1+f(3)\sqrt{1+\cdots}}}$

Hi i was wondering something about the great Ramanujan : I think moreover I'm not the only one who propose this kind of problem (so if you have a link related to this subject). We have : $$3=\sqrt{1+2\sqrt{1+3\sqrt{1+\cdots}}}$$ Now the problem : Let $f(x)$ be a positive,continuous and differentiable on function$(0,\infty)$ and non-constant then the functional equation : $$3=\sqrt{1+f(2)\sqrt{1+f(3)\sqrt{1+\cdots}}}$$ Have as unique solution $f(x)=x$ I have tried to build a counter-example without success .First it seems obvious for strictly increasing\decreasing functions such that $f(x)>x$ or $f(x)<x$. I would like to create an counter-example of the form : $$f(x)=x+g(x)$$ Where $g(x)$ is a periodic function . I have tried more general representation without success . If it's true we can see how Ramanujan was great . Any helps are highly appreciated . Thanks a lot .

Conjectured series representation of elliptic integral powers $K(k)^n$

This is a very simple question which has probably already been answered; I apologize if that is the case. We know that the following equation holds: $$K(k)=\frac{\pi}{2}\sum\limits_{n=0}^\infty a_n^{\;2}k^{2n}\tag{1}$$ where $a_n=\frac{(2n-1)!!}{(2n)!!}=\frac{(2n)!}{4^n(n!)^2}$. Additionally, we have that: $$K(k)^2=\frac{\pi^2}{4}\sum_{n=0}^\infty a_n^{\;3}(2kk')^{2n}\tag{2}$$ ($k'=\sqrt{1-k^2}$). Generalization to $K(k)^n$ seems a natural possibility. To slightly

support this, I have in the past formally derived (part of the derivation here although identity not explicitly stated) the following identity: $$\sum_{n=0}^{\infty}\frac{(2n)!^m}{(n!)^{2m}}x^n\\=\left(\frac{2}{\pi}\right)^{m-1}\int_0^\frac{\pi}{2}...\int_0^\frac{\pi}{2}\frac{1}{\sqrt{1-x\left(2^m\prod\limits_{k=1}^{m-1}\cos\theta_k\right)^2}}\;d\theta_1...d\theta_{m-1}\tag{3}$$ (please correct me if this formula is wrong); this is an $m-2$-tuple integral of an elliptic integral. A special case of this is: $$\sum_{n=0}^{\infty}\frac{(2n)!^3}{(n!)^{6}}x^n=\frac{4}{\pi^2}\int_0^\frac{\pi}{2}\int_0^\frac{\pi}{2}\frac{1}{\sqrt{1-64x\cos^2\theta\cos^2\varphi}}\;d\theta\;d\varphi\tag{4}$$ By comparing (2) and (4), we have: $$\int_0^\frac{\pi}{2}\int_0^\frac{\pi}{2}\frac{1}{\sqrt{1-64(kk')^2\cos^2\theta\cos^2\varphi}}\;d\theta\;d\varphi=K(k)^2\tag{5}$$ The symmetry of (5) makes me guess that the integrand can be split into a product of functions depending only on θ and φ and turned into a product of two elliptic integrals (although for some reason I cannot see how to do it and Wolfram Alpha won't check (5) for me). If this is indeed the case it makes me wonder whether the RHS of (3) may also be written as the product of $m-1$ complete elliptic functions $K(k)$ for some $k(x)$. In (2), $(kk')^2=k^2-k^4$, so I wonder in particular whether the following conjecture is true: $\forall m\in\mathbb{N}$ there exists a polynomial $\Pi_m(k)$ of order m^2 such that:
$$K(k)^m=\left(\frac{\pi}{2}\right)^m\sum_{n=0}^\infty a_n^{\;m+1}\Pi_m(k)^n\tag{*}$$ Question: Is $(*)$ true? If so, what is $\Pi_m(k)$? If not where does the pattern break down (if I am right in thinking that there is a pattern)?

Conjecture: every set of n equally spaced integers $\leq n^2$ contains a prime.

My claim: Any set of exactly n integers in the range $[1,n^2]$ which are an arithmetic sequence and share no common factor will contain at least one prime. Let $n\geq 2$ be a natural number, and let $a,b\in\mathbb{N}$ where $1\leq a \leq n$ and $1 \leq b \leq n^2$, such that $an+b\leq n^2$. Then the set $\{ax+b \mid 1 \leq x \leq n\}$ will contain between 1 and n primes, inclusive. There are three exceptions: $(n=12,a=1,b=113),(n=12,a=1,b=114),(n=13,a=1,b=113)$, but I strongly suspect those are the only ones. (You could eliminate them by requiring $a > 1$, but I don't think it's worth the cost in generality.) In a nutshell, this conjecture claims that given an $n \times n$ square, any line you draw (that intersects the integers appropriately) must contain a prime, including for starters all rows and columns-something I called the Rook Conjecture, but have since seen referred to as the Calendar Conjecture. I've empirically tested this out to $n=150$ or so, and the trend is strong enough that I'm almost sure it's correct. Of course, finding a proof is another story. I'm looking for feedback. Good answers would be: counterexamples indicating that this is previously known and/or conjectured providing reasons why this does or does not seem likely to be true any other insights

Is the following an existing conjecture or a conjecture at all?

the following floated to my mind today, can you verify if it stands to be true, or is a pre-existing conjecture. If not, can you correct me? And if it is one, can you prove it? Prime factorisation of any perfect square P of the form $$P=a_1^{x_1}\times a_2^{x_2}\times a_3^{x_3}\times.....\times a_n^{x_n} $$ where $$x_1,x_2≠0$$ which implies that atleast two non unity factors exist,then $$a_1^{x_1}+ a_2^{x_2}+ a_3^{x_3}+.....+ a_n^{x_n}=Z$$ where Z is perfect square, is only applicable for $P=144$. Example: for $P=144$, prime factorisation is as follows: $$2^4\times 3^2$$ and $$2^4+ 3^2=25=5^2$$

A pattern with third coefficients of sums of powers.

So I have heard countless times of Bernoulli Numbers and its relation to the sums of powers. Inspired by this (as well as Chebyshev polynomials), I decided to look at the sums of powers myself and find patterns in the coefficients. Let $$S_{n,k}=1^k+2^k+\cdots + n^k$$ then, thanks to wikipedia, these are the first five formulae. However, I will highlight the following. $$\begin{align}S_{n,1}&=\frac 12n^2 + \frac 12n\\S_{n,2}&=\frac 13n^3+\frac 12n^2+\color{red}{\frac 16}n\\ S_{n,3}&=\frac 14n^4+\frac 12n^3+\color{red}{\frac 14}n^2+0n\\ S_{n,4}&= \frac 15n^5+\frac 12n^4+\color{red}{\frac 13}n^3+0n^2-\frac 1{30}n\\S_{n,5}&=\frac 16n^6+\frac 12n^5+\color{red}{\frac 5{12}}n^4+0n^3-\frac{1}{12}n^2+0n\\&{\;}\vdots\end{align}$$ Let $R_k=$ the red coefficient of $S_{n,k}$. Then, it appears that, for all $m\in\{0,1,2,3,4\}$, we have $$R_{6+m}+R_{6-m}=1.$$ e.g. $R_6=\frac 12$, thus $m=0\Rightarrow \frac 12 + \frac 12 = 1$; and $R_7=\frac 7{12}$, thus $m=1\Rightarrow \frac 7{12}+\frac 5{12}=1$. Is there some kind of "reason" why this is happening? I mean, upon speculation, I think $R_k=\frac k{12}$ so if that is true, then my conjecture is true. How can this be (dis)proven? Any thoughts? Thanks. Incidentally, I did not include bernoulli-numbers because, although they may be related, I do not specifically focus on them in this question.

How do we prove this continued fraction for the quotient of gamma functions

Given complex numbers $a=x+iy$, $b=m+in$ and a gamma function $\Gamma(z)$ with $x\gt0$ and $m\gt0$, it is conjectured that the following continued fraction holds $$\frac{\displaystyle4\Gamma\left(\frac{2a+3}{4}\right)\Gamma\left(\frac{2b+3}{4}\right)}{\displaystyle\Gamma\left(\frac{2a+1}{4}\right)\Gamma\left(\frac{2b+1}{4}\right)}=\cfrac{(2a+1)(2b+1)}{a+b+2+\cfrac{(a-b+1)(b-a+1)}{a+b+4+\cfrac{(2a+3)(2b+3)}{a+b+6+\cfrac{(a-b+3)(b-a+3)}{a+b+8+\ddots}}}}\tag{1a}$$ Corollary $$\frac{4}{\pi}=\cfrac{(2)^2}{3+\cfrac{(1)^2}{5+\cfrac{(4)^2}{7+\cfrac{(3)^2}{9+\ddots}}}}\tag{1b}$$ Q: How do we

prove the continued fraction $(1a)$ rigorously?

Conjecture about Jensen's inequality and polynomials

Hi it's related to the following conjecture An inequality for polynomials with positives coefficients : We have the first conjecture : Let $x,y>0$ then we have : $$(x+y)f\Big(\frac{x^2+y^2}{x+y}\Big)(f(x)+f(y))\geq 2(xf(x)+yf(y))f\Big(\frac{x+y}{2}\Big)$$ Where :$$f(x)=\sum_{i=0}^{n}a_ix^i$$ And $a_0 \ge a_1 \ge ... \ge a_n>0$ (Thanks to p4sch) Second conjecture : Let $x_i>0$ be n real numbers then we have : $$(\sum_{i=1}^{n}x_i)f\Big(\frac{\sum_{i=1}^{n}x_i^2}{\sum_{i=1}^{n}x_i}\Big)(\sum_{i=1}^{n}f(x_i))\geq n(\sum_{i=1}^{n}x_if(x_i))f\Big(\frac{\sum_{i=1}^{n}x_i}{n}\Big)$$ Where :$$f(x)=\sum_{i=0}^{n}a_ix^i$$ And $a_0 \ge a_1 \ge ... \ge a_n>0$ It seems to be true in the case where $f(x)=\tan(x)$ see A sharp inequality for tangent (refinement of Jensen's inequality) I have tried the approach of River Li in the case $n=3$ without success . I think it's really hard and interesting since at the beginning I have put together two applications of Jensen's inequality . Putting $f(x)=e^x$ gives a nice refinement of Am-Gm (as applications). If it's true I would like just one approach to prove it . Any helps is greatly appreciated . Thanks a lot for all your contributions . Ps:Is it a good idea to put it on maths overflow ? Reference : https://en.wikipedia.org/wiki/Stable_polynomial

Prove a conjecture, balls in boxes, n steps

My uncle gave me the following problem to work on (just for fun), he doesn't know whether the problem has a solution. I haven't been able to solve it and I give up, I don't think my current knowledge is enough to solve it. Problem statement: Initially there are three boxes, labelled A, B and C. A contains $3n$ balls, with $n\geq 5$ a natural number. At step number k, one withdraws k balls from any box and place it into any other box. Show that it is always possible to end up with n balls in each boxes after exactly n steps. The first thing that came to my mind was induction. I.e. build a solution for $n+p$ given a solution for n. It turns out that this will not work because if we have a solution for a given n, then the step $k=n+1$ would be to withdraw $n+1$ balls from any box and place them into another box. However this would make the number of balls negative in a box, so this is not possible. Hence I think it is impossible to construct a solution based on another solution, i.e. just continue the game from the case where there was an equal amount of balls at step n. I have written a Python program to output the solutions for various n's, and I stared hard at the solutions to see whether there are "trivial" ones. I couldn't find such a thing. Sometimes there is a rather "simple looking" solution for a given n, but it is usually not that easy to guess either, and other times I cannot find such nice answers. By the way, the number of answers for a given n grows with n in a strange way (to me), that would make a nice problem on its own (i.e. determine the relationship between the number of solutions and n, but I might ask it in another question.). So I am thinking that maybe the problem can be tackled with number theory, i.e. by finding a methodical/algorithmic way to construct a solution for a given n that is not based on any solution for a lesser n. But I have no knowledge in number theory, so I am not even sure. I am curious to see if people here have ideas and possibly solution(s).

To prove the existence of solution(s) of $\frac{a}{b+c}+\frac{b}{a+c}+\frac{c}{a+b}=4$

To prove if a certain equation has a solution, we do not need necessarily solve that equation. Example: Is there any point of the curve $y=\sin^2(x)/x$ between $x=0$ and $x=\pi$ so that the slope of the tangent line at that point is zero? The answer is yes, because y is continuous, differentiable, and $y(0)=y(\pi)=0$ (limits take place). This is (Rolle's Theorem). And we are finish. We did not solve it and find where is that point. My question is about a false conjecture that the equation $$\frac{a}{b+c}+\frac{b}{a+c}+\frac{c}{a+b}=4$$ has no positive integer solutions for a,b,c. Without finding that/those solution(s), which is/are really large numbers, can we prove that the equation has a solution? In other words, can we prove the existence of solution(s) but not by giving an examples like: $a=154476802108746166441951315019919837485664325669565431700026634898253202035277999$ $b=368751317941299998271978115652254748254929799689719709962831374716372246340555795$ $c=437361267792869725786125260237139015281653755816161361862143799337842346777203 6$ The proof can be by contradiction, or direct proof, or any way. Thanks in advance

A conjectured upper bound for $\left(\frac{x^n+1}{x^{n-1}+1}\right)^n+\left(\frac{x+1}{2}\right)^n$ and $x\geq 1$

Hi I have (related https://mathoverflow.net/questions/337457/prove-that-left-fracxn1xn-11-rightn-left-fracx12-rightn): Let $x\geq 1$ a real number and $n\geq 2$ a natural number then we have : $$\Big(\frac{x^{n+1}+1}{x+1}\Big)\Bigg(\frac{\Big(\frac{x+1}{2}\Big)^n}{\Big(\frac{x^2+1}{x+1}\Big)^n}+\frac{(x^n+1)^2}{(x^{n-1}+1)(x^{n+1}+1)}\Bigg)\geq \left(\frac{x^n+1}{x^{n-1}+1}\right)^n+\left(\frac{x+1}{2}\right)^n$$ It's a conjecture so I have tested for $n\leq 20$. Maybe it works also for n a positive real number . If it's true I think we can make something similar to the Peter Mueller's answer. For the case $n=3$ here we have the derivative . Clearly the numerator (of the derivative) is positive for $x\geq 1$.But in some way it's not so easy with the general case . So how to solve it ? Any helps is greatly appreciated. Thanks in advance for all your contribution .

Is there an open mathematical conjecture which has been shown not to be provable in Peano Arithmetic before (possibly) being proved true?

There are several mathematical statements φ about the natural numbers which are known to be true and known not to be provable in Peano Arithmetic (c.f. Gödel's incompleteness theorem, Paris-Harrington theorem, Kirby-Paris theorem...). In all such instances I know of, φ was first shown to be true in "standard mathematical practice" and only later logicians showed that φ is not provable in PA. Is there any example of statement φ about the natural numbers which is not known to be true but already known not to be provable in PA? Or, at least, is there any such example which had such a status in the past (i.e., until actually being proven true)?

Conjectured upper bound $\frac{\Gamma(x+n)}{\Gamma(x)}$ and limit at infinity

Let $x\geq 1$ a real number and $n\geq 3$ a natural number then we have : $$\frac{\Gamma(x+n)}{\Gamma(x)}\leq \left(\frac{nx+\left(\frac{n(n-1)}{2}\right)}{\frac{n}{2}}-\left(x^x(x+1)^{x+1}(x+2)^{x+2}\cdots(x+n-1)^{x+n-1}\right)^{\frac{1}{nx+\left(\frac{n(n-1)}{2}\right)}}\right)^{n}$$ It's a conjecture but first for me :$\frac{\Gamma(x+n)}{\Gamma(x)}=x(x+1)\cdots(x+n-1)$.So if there are problems of notations feel free to correct me . I have tested for $n\leq 25$. If it's true I find this inequality beautiful . I conjecture also that the difference tends to 0 when x tends to infinity . I have tried Gautschi's inequality and more without success . Update 08/12/2026: GM and Gw are both of the form $a\bar{} \exp(f(u))$, where $u=\frac{1}{\bar a}$, with $f(u)=\sum_{j\geq 1}c_j u^j$, where $f(u)$ comes from the expansion of $\ln(1+d_k u)$. Faà di Bruno's formula then gives the coefficients of $\exp(f(u))$ in terms of the complete Bell polynomials B_n, evaluated at the derivatives of f. By the exact symmetry of $d_k=k-\frac{n-1}{2}$, namely the invariance under $k\mapsto n-1-k$, all odd moments $m_{2j+1}=\frac{1}{n}\sum_k d_k^{,2j+1}$ vanish exactly. Therefore, f contains only even powers of u, and consequently $G_M+G_w-2\bar a$ does as well. If you have an idea to solve it... Any helps is greatly appreciated . Thanks in advance for all your contributions .

A conjectured criterion for a generalized ramanujan tau function

Given Ramanujan tau function $\tau(n)$, which is the nth Fourier coefficient of the modular discriminant $\displaystyle \Delta(q)=q\prod_{m=1}^\infty (1-q^m)^{24} = \sum_{n=1}^\infty \tau(n)\,q^n\tag{1a}$ Nothing forbids us from generalizing the generating function to $\displaystyle \Delta_{k}(q)= \sum_{n=1}^\infty \tau((2k-1)n)\,q^n\tag{1b}$ for integers $k\gt0$ After some experimentation with wolfram mathematica, one discovers the following intriguing patterns $\Delta_{1}(q)=q^{\color{blue}{1}}-24q^2+252q^3-1472q^4+4830q^5-6048q^6-16744q^7+84480q^8-113643q^{\color{blue}{9}}-115920q^{10}+543612q^{11}-\cdots$ $\Delta_2(q)=252q-6048q^2-113643q^{\color{brown}{3}}-370944q^4+1217160q^5+2727432q^6-4219488q^7+21288960q^8-73279080q^9-29211840q^{10}+134722224q^{11}+167282496q^{12}-145589976q^{13}+101267712q^{14}-548895690q^{15}+248758272q^{16}-1740295368q^{17}+1758697920q^{18}+2686677840q^{19}-1791659520q^{20}+1902838392q^{21}-3233333376q^{22}+4698104544q^{23}-9600560640q^{24}-6425804700q^{25}+3494159424q^26+1665188361q^{\color{brown}{27}}+\cdots$ $\vdots$ From which we deduce the following conjecture The nth coefficient $\tau((2k-1)n)$ is odd if and only if the powers of q in the generating function $(1b)$ are $n\stackrel{\mathrm{def}}{=} \begin{cases}{\color{brown}{(2k-1),9(2k-1),25(2k-1),49(2k-1),...}} & \mbox{ where $2k-1=1,3,5,7,11,13,...$ is any odd square-free integer}\\ \end{cases}$ Or stated differently $\displaystyle\sum_{n=1}^\infty \tau((2k-1)n) q^{n}\equiv \sum_{m=1}^\infty q^{(2k-1)(2m-1)^2}\bmod 2$ for positive integers k That is, $\tau((2k-1)n)$ is odd iff the powers of q in $(1b)$ are $n=(2k-1)(2m-1)^2$ given that $(2k-1)$ is any odd square-free integer valid for $k\gt0$ Question: How do we prove the conjectured criterion? Remark: The Möbius function $\mu(n)$ is either 1 or -1 if n is square-free depending on whether it has a number of even prime factors or odd respectively and $\mu(n)=0$ if it is non square-free. It happens to be a very important arithmetic function in number theory. For example, the Dirichlet series that generates the Möbius function is the reciprocal of the Riemann zeta function $\displaystyle \sum_{n=1}^{\infty} \frac{\mu(n)}{n^s}=\frac{1}{\zeta(s)}$. The fact that this conjectured congruence has something to do with the möbius function is exactly what makes it interesting.

Little conjecture in elementary number theory

I was calcultaing quadratic residues. I noticed nice pattern: quadratic residues modulo p^n where p is prime are well-behaved; they always repeat after $\frac{p^n - 1}{2}$-th place (starting with $1^2 \equiv 1 \pmod {p^n}$. I know this is proven for $n = 1.$ Also, I noticed that many composite numbers have random-looking quadratic residues. I found only few exception: 10 (1, 4, 9, 6, 5, 6, 9, 4, 1), 6 (1, 4, 3, 4, 1). Three examples for $n = 2$: (1) $p = {2^2} = 4$: 1, 0, 1, 0, etc. (2) $p = {5^2} = 25$: 1, 4, 9, ..., 19, 19, ... 9, 4, 1. (3) $p = 3^2 = 9$: 1, 4, 0, 7, 7, 0, 4, 1. Two examples for $n = 3$: (1') $p = 2^3 = 8$: 0, 1, 4, 1, 0, 1, 4, 1. (2') $p = 3^3 = 27$: 1, 4, 9, 16, 25, 9, ..., 7, 7 ... 9, 25, 16, 9, 4, 1. So, I see that residues can repeat (see example (2')) but they always have this property that sequance repeat after half terms. Is there proof of this?

Conjecture on $\pi(n)$ and other arithmetic functions

Notations Let $\pi(n)$ be the prime countiong function. Let $\alpha(n)$ denote the number of prime factors of n and $\beta(n)$ the sum of the prime factors of n. In other words, if $$n=p_1^{x_1}p_2^{x_2}...p_m^{x_m}$$ then $\alpha(n)=m$ and $\beta(n)=p_1+p_2+...+p_m$ (I changed the notations; It was pointed out in the comments that ψ and ω are other functions and they were misleading) Statement Let $\pi(n)$ be the prime counting function, $\psi(n)$ the number of prime factors and $\omega(n)$ the sum of the prime factors of n. Prove or disprove that there are infinitely many n such that: $$\pi(n)=\alpha(n)\beta(n)$$ $\text{Some other observations}$ Here are the first solutions: 4, 120, 437, 546, 620, 8144, 11509, 170049, 170907, 340655, 478476, 789575 Also, if we use the Prime Number Theorem ($\pi(n)$ is aproximatively $\frac{n}{\ln(n)}$) we can derive solutions in an exhaustive manner. For example, find at what point $\frac{n}{\pi(n)}$ is aproximatively $\frac{47}{2}$ and then subtract 47 from n until you get the solution. Using this method we get 45764089927 which in fact works. $\text{Why is it an interesting problem?}$ I find it rather interesting due to the unusual relationship between these 3 functions. I played a while with several arithmetic functions and couldn't find strong conection between them, but the equation $\pi(n)=\alpha(n)\cdot\beta(n)$ seems promising.

Conjecture on the sum of prime factors

Notations Let $\pi(n)$ be the prime counting function. Let denote $\alpha(n)$ the sum of the prime factors of n. (i.e. In other words, if $$n=p_1^{x_1}p_2^{x_2}...p_m^{x_m}$$ then $\alpha(n)=p_1+p_2+...+p_m$.) (I changed the notation; It was pointed out in the comments that ω is another function and it was misleading) Statement Find whether the equation $\alpha(n)+1|n+1$ has infinitely many squarefree solutions. Moreover, show that one can find an infinitude of composite, non-squarefree solutions. Progress The original question was posted here and Peter found the following general solution for non-squarefree integers: Claim : $n=2\cdot 3\cdot 5^{5m+4}$ is a solution for all $m\ge 1$ Proof : The sum of the prime factors is obviously 10. Because of $5^5\equiv 1\mod 11$, we have $n\equiv 2\cdot 3\cdot 5^4\equiv -1\mod > 11$, hence $11\mid n+1$ Hence there are infinite many solutions. So it has been proven that there are in fact infinitely many non-squarefree solutions (and the prime numbers are trivial solutions). The question about composite squarefree solutions still holds.

Problem from Discrete Mathematics and its application for Rosen section 4.4

This exercise outlines a proof of Fermat’s little theorem. a) Suppose that a is not divisible by the prime p. Show that no two of the integers 1 · a, 2 · a, . . . , (p - 1)a are congruent modulo p. b) Conclude from part (a) that the product of 1, 2, . . . , p - 1 is congruent modulo p to the product of a, 2a, . . . , (p - 1)a. Use this to show that (p - 1)! ≡ a p-1 (p - 1)! (mod p). I already solved the first problem (a) but I couldn't solve Problem (b) So can any one please help me to solve it, mean problem (b) ? Note : I can't use Fermat’s little theorem to prove it as this problem is to prove the Fermat’s little theorem

Conjecture on prime generating sequence

Statement Denote p_n the nth prime. Consider the set $$\mathcal{P}=\{\sum_{i=1}^np_i:n\in\mathbb{N}\}$$ Prove that $|\mathcal{P}\cap\mathbb{P}|=\infty$ $\text{Why am I studying this}$ First of all, I find it an itriguing and rather unusual result. I also want to see how we can generate primes by adding numbers, so this was a natural idea. To conclude, I also highly highly suspect these primes have some extra properties from normal ones. $\text{Computational arguments}$ First of all, here are the first 200 values for $\sum_{i=1}^{n}p_i$: 5 10 17 28 41 58 77 100 129 160 197 238 281 328 381 440 501 568 639 712 791 874 963 1060 1161 1264 1371 1480 1593 1720 1851 1988 2127 2276 2427 2584 2747 2914 3087 3266 3447 3638 3831 4028 4227 4438 4661 4888 5117 5350 5589 5830 6081 6338 6601 6870 7141 7418 7699 7982 8275 8582 8893 9206 9523 9854 10191 10538 10887 11240 11599 11966 12339 12718 13101 13490 13887 14288 14697 15116 15537 15968 16401 16840 17283 17732 18189 18650 19113 19580 20059 20546 21037 21536 22039 22548 23069 23592 24133 24680 25237 25800 26369 26940 27517 28104 28697 29296 29897 30504 31117 31734 32353 32984 33625 34268 34915 35568 36227 36888 37561 38238 38921 39612 40313 41022 41741 42468 43201 43940 44683 45434 46191 46952 47721 48494 49281 50078 50887 51698 52519 53342 54169 54998 55837 56690 57547 58406 59269 60146 61027

If $N = q^k n^2$ is an odd perfect number with special prime q, then can N be of the form $q^k \cdot (\sigma(q^k)/2) \cdot {n}$?

Let $\sigma(x)$ denote the sum of divisors of the positive integer x. A number M is said to be perfect if $\sigma(M)=2M$. For example, 6 and 28 are perfect since $$\sigma(6) = 1 + 2 + 3 + 6 = 2\cdot{6}$$ and $$\sigma(28) = 1 + 2 + 4 + 7 + 14 + 28 = 2\cdot{28}.$$ It is currently unknown if there are infinitely many even perfect numbers. It is also an open problem whether any odd perfect numbers exist. It is widely believed that there are no odd perfect numbers. Euler proved that an odd perfect number N, if one exists, must necessarily have the so-called Eulerian form $$N = q^k n^2$$ where q is the special/Euler prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. QUESTION Here is my question: Can the odd perfect number N be of the form $$\frac{q^k \sigma(q^k)}{2}\cdot{n}?$$ I would certainly appreciate it if anybody could point me to papers/articles/publications in the literature where this particular inquiry is covered. CONTEXT Slowak (1999) proved that the odd perfect number N must be of the form $$\frac{q^k \sigma(q^k)}{2}\cdot{d},$$ where $d > 1$. Dris (2017) showed further that d must have the form $$\frac{D(n^2)}{\sigma(q^{k-1})}=\gcd(n^2,\sigma(n^2))=\frac{\sigma(n^2)}{q^k}=\frac{n^2}{\sigma(q^k)/2},$$ where $D(x)=2x-\sigma(x)$ is the deficiency of x.

On Erdös-Szekeres convex polygons lower bound

I have problems with the construction of 2^{n-2} points that contain no n-gon, particulary, the proof of the book "Open Problems in Mathematics". The proof sais that: For $i = 0, ..., n-2$ let T_i be a set of ${{n-2}\choose i}$ points in general position in the plane, containing no $i+2$-cap and no $n-i$-cup and having the property that no two points in the set are connected by a line having slope of absolute value greater than 1. (The existence of T_i follows from a previous theorem, and the condition on slopes can be satisfied by “compressing” T_i vertically.) Place a small copy of T_i in a neighborhood of the point on the unit circle making an angle of $\frac{\pi}{4} - \frac{i\pi}{(n-2)2}$ with the positive x-axis. Let X be the union of $T_1, T_2, ..., T_{n-2}$. Clearly, $|X| = 2^{n-2}$. Suppose that Y is a convexly independent subset of X. Let k and l be the smallest and the largest values of i so that $Y\cap T_i\neq \emptyset$. If $k=l$, then Y contains no $k+2$-cap and no $n-k$-cup. The construction guarantees that: $Y \cap T_k$ is a cap of at most $k + 1$ points, $Y \cap T_l$ is a cup of at most $n + l- 1$ points, $|Y \cap T_i|\leq 1$ for all $i = k + 1, ..., l-1$ Summing up, $|Y| = (k + 1) + (l + k - 1) + (n -l - 1) = n-1$. I understood all the reasoning except the part that say: $|Y\cap T_i|\leq 1$ for all $k+1\leq i\leq l-1$. Why in the middle sets the intersection with Y have at least one element?

Reference request for conjecture about bridge and crossing number of knots

Murasugi in his book (Knot theory and its applications, page 60) writes: Conjecture. If K is a knot, then $c(K) \ge 3(br(K) - 1)$, where equality only holds when K is the trivial knot, the trefoil knot, or the (connected) sum of trefoil knots. I would like to know who came up first with this conjecture, if there was any progress on it in recent years and if it has some special name. Murasugi's book is quite tacit here.

Pretty conjecture $x^{\left(\frac{y}{x}\right)^n}+y^{\left(\frac{x}{y}\right)^n}\leq 1$

inspired (again) by an inequality of Vasile Cirtoaje I propose my own conjecture : Let $x,y>0$ such that $x+y=1$ and $n\geq 1$ a natural number then we have : $$x^{\left(\frac{y}{x}\right)^n}+y^{\left(\frac{x}{y}\right)^n}\leq 1$$ First I find it very nice because all the coefficient are 1 . I have tested with Geogebra until $n=50$ without any counter-examples. Furthermore we have an equality case as $x=y=0.5$ or $x=1$ and $y=0$ and vice versa . To solve it I have tried all the ideas here My main idea was to make a link with this inequality (my inspiration) see here So if you can help me to solve it or give me

an approach... ...Thanks for all your contributions ! Little update I think there is also an invariance as in question here Conjecture $a^{(\frac{a}{b})^p}+b^{(\frac{b}{a})^p}+c\geq 1$ Theoretical method Well,Well this method is very simple but the result is a little bit crazy (for me (and you ?)) Well ,I know that if we put $n=2$ we can find (using parabola) an upper bound like $$x^{\left(\frac{1-x}{x}\right)^2}\leq ax^2+bx+c=p(x)$$ And $$(1-x)^{\left(\frac{x}{1-x}\right)^2}\leq ux^2+vx+w=q(x)$$ on $[\alpha,\frac{1}{2}]$ with $\alpha>0$ and such that $p(x)+q(x)<1$ In the neightborhood of 0 we can use a cubic . Well,now we have (summing) : $$x^{\left(\frac{1-x}{x}\right)^2}+(1-x)^{\left(\frac{x}{1-x}\right)^2}\leq p(x)+q(x)$$ We add a variable ε such that $(p(x)+\varepsilon)+q(x)=1$ Now we want an inequality of the kind ($k\geq 2$): $$x^{\left(\frac{1-x}{x}\right)^{2k}}+(1-x)^{\left(\frac{x}{1-x}\right)^{2k}}\leq (p(x)+\varepsilon)^{\left(\frac{1-x}{x}\right)^{2k-2}}+q(x)^{\left(\frac{x}{1-x}\right)^{2k-2}}$$ Now and it's a crucial idea we want something like : $$\left(\frac{x}{1-x}\right)^{2k-2}\geq \left(\frac{1-(p(x)+\varepsilon)}{q(x)}\right)^y$$ AND : $$\left(\frac{1-x}{x}\right)^{2k-2}\geq \left(\frac{1-q(x)}{p(x)+\varepsilon}\right)^y$$ Now it's not hard to find a such y using logarithm . We get someting like : $$x^{\left(\frac{1-x}{x}\right)^{2k}}+(1-x)^{\left(\frac{x}{1-x}\right)^{2k}}\leq q(x)^{\left(\frac{1-q(x)}{q(x)}\right)^{y}}+(1-q(x))^{\left(\frac{q(x)}{1-q(x)}\right)^{y}}$$ Furthermore the successive iterations of this method conducts to 1 because the values of the differents polynomials (wich are an approximation of the initial curve) tend to zero or one (as abscissa). The extra-thing (and a little bit crazy) we can make an order on all the values. My second question Is it unusable as theoretical\practical method ?

If a is deficient-perfect, can ab be deficient-perfect if $b > 1$, and ab is odd?

Let $\sigma(x)$ denote the sum of divisors of the positive integer x. The deficiency of x is given by the formula $$D(x)=2x-\sigma(x).$$ A number y is said to be deficient-perfect if $D(y) \mid y$. Note that a deficient-perfect number z is automatically deficient (i.e., z satisfies $D(z) \geq 1$). Here is my question: If a is deficient-perfect, can ab be deficient-perfect if $b > 1$, and ab is odd? The reason for the condition $ab \equiv 1 \pmod 2$ is to exclude the case $$(a_1,b_1)=\bigg(2^k,2^{k+1}+2^t-1\bigg),$$ where $2^{k+1}+2^t-1$ is an odd prime and $t \leq k$, as well as the case $$(a_2,b_2)=(2^r,2^s).$$ MY ATTEMPT Let ab be odd. This implies that a is odd and b is odd. Let a be deficient-perfect, and suppose to the contrary that ab is also deficient-perfect, where $b>1$. Then we have the divisibility constraints $$D(a) \mid a \iff a = (2a - \sigma(a))c$$ $$D(ab) \mid ab \iff ab = (2ab - \sigma(ab))d$$ Substituting the first equation into the variable a in the LHS of the second equation, we obtain $$(2a - \sigma(a))bc = (2ab - \sigma(ab))d \iff 2abc - bc\sigma(a) = 2abd - d\sigma(ab)$$ $$\iff 2ab(c-d) = bc\sigma(a) - d\sigma(ab).$$ But $$c - d = \frac{a}{D(a)} - \frac{ab}{D(ab)} = a\cdot\bigg(\frac{D(ab)-bD(a)}{D(a)D(ab)}\bigg) = a\cdot\bigg(\frac{2ab-\sigma(ab)-2ab+b\sigma(a)}{D(a)D(ab)}\bigg)$$ $$=a\cdot\bigg(\frac{-\sigma(ab)+b\sigma(a)}{D(a)D(ab)}\bigg)$$ which implies that $c - d \leq 0$ since $$b\sigma(a) \leq \sigma(ab).$$ We therefore conclude that $$2ab(c-d) = bc\sigma(a) - d\sigma(ab) \leq 0.$$ Alas, this is where I get stuck. Postscript: Note that $$\mathscr{D} = 9018009 = {3^2}\cdot{7^2}\cdot{{11}^2}\cdot{{13}^2}$$ is the lone odd deficient-perfect number that we know of, to this day. So essentially, the question asks whether we could produce another odd deficient-perfect number from $\mathscr{D}$ (via multiplying $\mathscr{D}$ by $\mathscr{D'} > 1$), or if it could be proven that this is impossible.

$\pi(n)$ is always more than the sum of the prime indices of the factors of composite $n \geq 12$

Let $n=p_1^{a_1} p_2^{a_2} \cdots p_k^{a_k} \geq 12$ be any composite integer. Then it seems that this is true: $$\pi(n) > \sum_{i=1}^{k}{\pi(p_i)a_i}\ .$$ You get equality instead iff n is prime. I also assume that if it is true, it's a known result. Can anyone point me towards a resource discussing it if so? Alternatively, if I've made a mistake and/or this is a trivial result, please point out how. Also, if true, I think Bertrand's Postulate immediately follows: For prime p, it gives $\pi(2p)>\pi(p)+1$, implying at least one prime between p and $2p$. By the same token, $\pi(3p)>\pi(p)+2$, and $\pi(p^2)>2 \pi(p)$. (See my answer below for additional thoughts.)

Is this a valid proof for $I(n^2) \geq \frac{5}{3}$, if $q^k n^2$ is an odd perfect number with special prime q?

Let $\sigma(x)$ denote the sum of divisors of the positive integer x, and let $I(x)=\sigma(x)/x$ be the abundancy index of x. Note that both σ and I are multiplicative functions. A number m is said to be perfect if $\sigma(m)=2m$. Equivalently, $I(m)=2$. Euler proved that an odd perfect number, if one exists, must have the form $$m = q^k n^2$$ where q is the special prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Since q is prime, we have $$\frac{q+1}{q} = I(q) \leq I(q^k) = \frac{\sigma(q^k)}{q^k} = \frac{q^{k+1} - 1}{q^k (q - 1)} < \frac{q^{k+1}}{q^k (q - 1)} = \frac{q}{q - 1}$$ from which it follows that $$\frac{2(q-1)}{q} < I(n^2) = \frac{2}{I(q^k)} \leq \frac{2q}{q+1}.$$ Note that we then have the lower bound $$I(n^2) > \frac{2(q-1)}{q} \geq \frac{8}{5}$$ since q is a prime satisfying $q \equiv 1 \pmod 4$. Here is my initial question: Can we improve the lower bound for $I(n^2)$ to $$I(n^2) \geq \frac{5}{3}$$ using the following argument? $$\bigg(\frac{2q}{q+1} \geq I(n^2) > \frac{5}{3}\bigg) \implies q > 5 \implies q \geq 13 \implies \bigg(I(n^2) > \frac{2(q-1)}{q} \geq \frac{24}{13} > \frac{5}{3}\bigg)$$ Thus, we

have the biconditional $$I(n^2) > \frac{5}{3} \iff q > 5.$$ Next, we have the implication $$I(n^2) = \frac{5}{3} \implies q = 5.$$ It then suffices to prove the implication $$q = 5 \implies I(n^2) = \frac{5}{3}$$ to finally show that $$I(n^2) \geq \frac{5}{3},$$ since $q \geq 5$ holds. But note that, if $q=5$, then $$\frac{5}{3} = I(n^2) = \frac{2}{I(5^k)} = \frac{2\cdot{5^k}(5-1)}{5^{k+1}-1}$$ which implies that the Descartes-Frenicle-Sorli Conjecture that $k=1$ holds. Still, notice that we have $$k=1 \implies I(q^k) = I(q) = \frac{q+1}{q} = 1 + \frac{1}{q} \leq \frac{6}{5} \implies I(n^2) = \frac{2}{I(q^k)} = \frac{2}{I(q)} \geq \frac{2\cdot{5}}{6} = \frac{5}{3},$$ which is what we set out to prove. Here is my final question: Would it be possible to remove the reliance of the proof on the Descartes-Frenicle-Sorli Conjecture?

Properties of subsets for which $\sum 1/k$ diverges

The well-known Erdos-Turan conjecture is the following. Let $V \subset \mathbb{N}$ be such that $\sum_V k^{-1}$ diverges. Then V contains arithmetic progressions of every possible length. A recent result showed such a set V must contain infinitely many length-3 progressions. I am wondering: if $V \subset \mathbb{N}$ is such that $\sum_V k^{-1}=\infty$, what are some properties of V? This Wikipedia page gives a small number of properties, but I am curious whether there are others (being non-trivial).

Proving $\pi(ab) \geq \pi(a)\pi(b)$?

It occurs to me that a stronger version of my related post the other day would be: $$\pi(ab) \geq \pi(a) \cdot \pi(b)\ ,$$ which I believe holds for all naturals a,b except for the two pairs $(5,7)$ and $(7,7)$. My first thought on a proof was to point out that $$\pi(ab)\sim\frac{ab}{\log(ab)}>\frac{ab}{\log(a)\log(b)}\sim \pi(a)\pi(b)\ ,$$ given $a>e$ and $b>a^{1-\log{a}}$ to rule out the small log problems, though I'm not sure that's necessary. My question is whether that's enough to establish that the conjecture is always true for sufficiently large ab, or if it merely implies that it will tend towards being true in the limit. If this isn't enough and someone has a different way to go at it, I'd be interested to hear it. And if this approach is valid, is it safe to change the conjecture to the stricter $\pi(ab)>\pi(a)\pi(b)$ (for large enough ab)?

Conjecture about graph with points and arrows with weights

Postulates Each point has arrow(s), and each arrow is pointing to another point. An arrow of a point cannot point to itself. Arrows can only point to any direction on the right. That means $\uparrow$, $\downarrow$ are not allowed, and of course $\leftarrow$ is not allowed. Each arrow has a number x on it with $0<x<1$ and $x\in\mathbb{R}$. Of a point, say A, arrows pointing out to the right must have their numbers summing up to 1, only if the arrows exist. (That means if a point does not have arrows pointing to the right, the condition does not have to be satisfied) Same for arrows pointing to A. Conjecture Suppose there are a few points and arrows. Prove that if there are some points each with some arrows pointing to the right, there must be the same case but being pointed from the left, in order to satisfy the conditions listed above. (At least this is the pattern I can see.) For example, if there are 2 points each with 3 arrows each pointing to another point, there must be two points each being pointed with 3 arrows. I think it is related to Graph Theory, but I have no idea of proving it, or better say I am not familiar with Graph Theory. Evidences Example 1: There exists $A\xrightarrow{1} B$. Since there is 1 point with 1 arrow pointing to another point, there must be and there is 1 point being pointed with 1 arrow. Example 2: point A and B both have two arrows pointing to C and D. Hence, both point C and D are being pointed by two arrows from A and B. Example 3: point A and C both have two arrows pointing out, so two points D and F are being pointed by two arrows. point B has three arrows pointing out, so a point E is being pointed by three arrows. This graph also satisfies the conditions above: For point A: $0.8+0.2=1$ For point B: $0.2+0.3+0.5=1$ For point C: $0.3+0.7=1$ For point D: $0.8+0.2=1$ For point E: $0.2+0.3+0.5=1$ For point F: $0.3+0.7=1$ These are just simple cases. The conjecture will not be obvious or maybe even false in more complex graphs.

Rare interesting primes such as Wolstenholme and Wieferich primes

Take a look at the following two examples of "rare interesting primes"; Wolstenholme prime is a special prime number related to a stronger version of Wolstenholme's theorem. They have connections to Fermat's last theorem. The only known such primes are 16843 and 2124679, but it is believed (conjectured) that there are infinitely many. The corresponding OEIS sequence is A088164. Definition. A Wolstenholme prime is a prime number $p > 7$ that satisfies the congruence $$\left(\begin{array}{l}2 p-1 \\p-1\end{array}\right) \equiv 1 \quad\left(\bmod p^{4}\right).$$ Wieferich prime is a prime number related to a stronger version of Fermat's little theorem. They appear in works pertaining to Fermat's last theorem. The only known such primes are 1093 and 3511, but it is believed that there are infinitely many. The corresponding OEIS sequence is A001220. Definition. Wieferich prime is a prime number p such that p^2 divides $2^{p - 1} - 1$. I was wondering, Question. Are there any other types of "rare interesting primes"? I.e. primes related to known results in number theory and have been studied (there exist compelling references, i.e. such primes are "interesting"), but do not have many examples (are "rare"). For non-example, Twin primes are "interesting", but are not "rare" since one can easily list say 10^4 examples.

For example, Fermat primes are "interesting" and are "rare". Only known are $3, 5, 17, 257, 65537$. It is conjectured that these are the only terms (unlike the Wolstenholme and Wieferich primes). Another example may be of Mersenne Primes. We can list around 50 examples at the moment, where the largest example holds the current record for the largest prime. Are there any other examples?

A conjecture about Catalan sequence

For $n=2$, consider the free abelian group generated by polynomials corresponding to $\frac{(2 n)!}{2^n n!}=3$ partitions of $2n=4$ vertices into pairs (chords): $$ (x_1-x_3)(x_2-x_4),(x_1-x_2)(x_3-x_4),(x_1-x_4)(x_2-x_3) $$ Euler's Identity: $ (x_1-x_3)(x_2-x_4)=(x_1-x_2)(x_3-x_4)+(x_1-x_4)(x_2-x_3)$. So$\{(x_1-x_2)(x_3-x_4),(x_1-x_4)(x_2-x_3)\}\tag1\label2$$ is a basis. So the rank of the free abelian group is 2. For $n=3$, consider the free abelian group generated by polynomials corresponding to $\frac{(2 n)!}{2^n n!}=15$ partitions of $2n=6$ vertices into pairs (chords): \begin{array}r \{(x_1-x_2) (x_3-x_4) (x_5-x_6),\\(x_1-x_2) (x_3-x_5) (x_4-x_6),\\(x_1-x_2) (x_4-x_5) (x_3-x_6),\\(x_1-x_3) (x_2-x_4) (x_5-x_6),\\(x_1-x_3) (x_2-x_5) (x_4-x_6),\\(x_1-x_3) (x_4-x_5) (x_2-x_6),\\(x_2-x_3) (x_1-x_4) (x_5-x_6),\\(x_1-x_4) (x_2-x_5) (x_3-x_6),\\(x_1-x_4) (x_3-x_5) (x_2-x_6),\\(x_2-x_3) (x_1-x_5) (x_4-x_6),\\(x_2-x_4) (x_1-x_5) (x_3-x_6),\\(x_3-x_4) (x_1-x_5) (x_2-x_6),\\(x_2-x_3) (x_4-x_5) (x_1-x_6),\\(x_2-x_4) (x_3-x_5) (x_1-x_6),\\(x_3-x_4) (x_2-x_5) (x_1-x_6)\} \end{array} Using Euler's Identity we can decompose the product of intersecting chords into the sum of products of the non-intersecting chords. For example $(x_1-x_4)(x_2-x_5)(x_3-x_6)$ as in Fuhrmann's Theorem, There are 5 partitions of 6 vertices into non-intersecting chords $$\tag2\label1\begin{array}l\{(x_1-x_6)(x_2-x_5)(x_3-x_4),\\ (x_1-x_6)(x_2-x_3)(x_4-x_5),\\ (x_1-x_4)(x_2-x_3)(x_5-x_6),\\(x_1-x_2)(x_3-x_6)(x_4-x_5),\\(x_1-x_2)(x_3-x_4)(x_5-x_6)\}\end{array}$$ Under lexicographic order, the leading terms of \eqref{1} are distinct: $\{x_1x_2x_3,x_1x_2x_4,x_1x_2x_5,x_1x_3x_4,x_1x_3x_5\}$. Suppose $c_1(x_1-x_6)(x_2-x_5)(x_3-x_4)+\dots+c_5(x_1-x_2)(x_3-x_4)(x_5-x_6)=0$ for some $c_1,\dots,c_5\in\mathbb{Z}$. Comparing coefficients of term $x_1x_2x_3$ to get $c_1=0$, comparing coefficients of term $x_1x_2x_4$ to get $c_2=0$, comparing coefficients of term $x_1x_2x_5$ to get $c_3=0$, comparing coefficients of term $x_1x_3x_4$ to get $c_4=0$, comparing coefficients of term $x_1x_3x_5$ to get $c_5=0$, so $c_1=\dots=c_5=0$, \eqref{1} is linearly independent. So the rank of the free abelian group is 5. Here is a proof that the number of non-intersecting chords is Catalan number $\frac1{n+1}\binom{2n}n$. Each polynomial in \eqref{1} can be written as a $2×n$ "non-intersecting tableaux" $$ \Biggl\{\begin{array}{|c|c|}\hline1&2&3\\\hline6&5&4\\\hline\end{array}, \begin{array}{|c|c|}\hline1&2&4\\\hline6&3&5\\\hline\end{array}, \begin{array}{|c|c|}\hline1&2&5\\\hline4&3&6\\\hline\end{array}, \begin{array}{|c|c|}\hline1&3&4\\\hline2&6&5\\\hline\end{array}, \begin{array}{|c|c|}\hline1&3&5\\\hline2&4&6\\\hline\end{array}\Biggr\} $$ To show that a "non-intersecting tableux" is determined by its first row, we give a procedure to fill in the second row. For example $\begin{array}{|c|c|}\hline1&2&5&7\\\hline?&?&?&?\\\hline\end{array}$ to fill $3,4,6,8$ in the second row such that there are no intersecting chords, we must put 3 under the largest number less than $3:\begin{array}{|c|c|}\hline1&2&5&7\\\hline?&3&?&?\\\hline\end{array}$ then we must put 4 under the largest remaining number less than $4:\begin{array}{|c|c|}\hline1&2&5&7\\\hline4&3&?&?\\\hline\end{array}$, then we must put 6 under the largest remaining number less than $6:\begin{array}{|c|c|}\hline1&2&5&7\\\hline4&3&6&?\\\hline\end{array}$, then we must put 8 under the largest remaining number less than $8:\begin{array}{|c|c|}\hline1&2&5&7\\\hline4&3&6&8\\\hline\end{array}$ For all n we have shown the first rows of $\frac1{n+1}\binom{2n}n$ number of "non-intersecting tableaux" are distinct. Under lexicographic order, the leading terms of \eqref{1} correspond to the first row of tableaux, so the leading terms are distinct, so the set of polynomials corresponding to "non-intersecting tableux" are linearly independent for all n. So we have proved: For all n, the rank of the above free abelian group in $2n$ variables is $\frac1{n+1}\binom{2n}n$. For $n=4$, similarly decompose the product of intersecting chords into the sum of products of the non-intersecting chords. For example $(x_1-x_5)(x_2-x_6)(x_3-x_7)(x_4-x_8)$ As you can see, there will be two identical pairs in the end, so after collecting terms there will be two terms with coefficient 2 \begin{align} (x_1 - x_5)(x_2 - x_6)(x_3 - x_7)(x_4 - x_8)\\ = (x_1 - x_4)(x_2 - x_3)(x_5 - x_8)(x_6 - x_7)\\ + \color{red}{2}(x_1 - x_8)(x_2 - x_3)(x_4 - x_5)(x_6 - x_7)\\ + (x_1 - x_2)(x_3 - x_8)(x_4 - x_7)(x_5 - x_6)\\ + (x_1 - x_2)(x_3 - x_8)(x_4 - x_5)(x_6 - x_7)\\ + \color{red}{2}(x_1 - x_2)(x_3 - x_4)(x_5 - x_6)(x_7 - x_8)\\ + (x_1 - x_2)(x_3 - x_4)(x_5 - x_8)(x_6 - x_7)\\ + (x_1 - x_4)(x_2 - x_3)(x_5 - x_6)(x_7 - x_8)\\ + (x_1 - x_8)(x_2 - x_3)(x_4 - x_7)(x_5 - x_6)\\ + (x_1 - x_2)(x_3 - x_6)(x_4 - x_5)(x_7 - x_8)\\ + (x_1 - x_8)(x_2 - x_7)(x_3 - x_4)(x_5 - x_6)\\ + (x_1 - x_8)(x_2 - x_7)(x_3 - x_6)(x_4 - x_5)\\ + (x_1 - x_8)(x_2 - x_5)(x_3 - x_4)(x_6 - x_7)\\ + (x_1 - x_6)(x_2 - x_3)(x_4 - x_5)(x_7 - x_8)\\ + (x_1 - x_6)(x_2 - x_5)(x_3 - x_4)(x_7 - x_8)\end{align} Conjecture. Express $(x_1-x_{n+1})(x_2-x_{n+2})\dots(x_n-x_{2n})$ as a linear combination of polynomials corresponding to the non-intersecting chords, then the term $(x_1-x_2)(x_3-x_4)\cdots(x_{2n-1}-x_{2n})$ and the term $(x_{2n}-x_1)(x_2-x_3)\cdots(x_{2n-2}-x_{2n-1})$ have largest coefficient in absolute value. Mathematica code to compute the largest coefficients in absolute value Needs["Combinatorica`"]; coeff[n_]:=Max[Abs[PolynomialReduce[Product[Indexed[x,i]-Indexed[x,n+i],{i,n}],Table[Module[{t1=t[[1]],t2=t[[2]],poly=1,i=1},Do[i=1;While[Length[t1]>i&&t1[[i+1]]<t2[[1]],i++];poly*=Indexed[x,t1[[i]]]-Indexed[x,t2[[1]]];t1=Delete[t1,i];t2=Rest[t2],n];poly],{t,Tableaux[Table[n,2]]}],Table[Indexed[x,i],{i,2n}]][[1]]] the terms $n=2,\dots,9$ in the sequence agree with A099960: \begin{array}{c|c} n&2&3&4&5&6&7&8&9\\\hline \text{largest abs coefficient}&1&1&2&3&8&17&56&155 \end{array}

Can composition of integer polynomial and rational polynomial with a non-integer coefficient result in integer polynomial?

Can we find two polynomials $p(x)$ and $q(x)$, where $p(x)$ is a non-constant monic polynomial over integers and $q(x)$ is a monic polynomial over rationals with at least one non-integer coefficient, such that their composition $p(q(x))$ is a polynomial over integers? If not, how to prove it? For example let $q(x)=x^2+\frac{1}{2}x+1$ and $p(x)=x^3+a_2x^2+a_1x+a_0$, then $p(q(x))=x^6+\frac{3}{2}x^5+\dots$, so no matter what integers a_i we choose, the resulting polynomial will have a non-integer coefficient. The monic condition is important, since otherwise we could multiply $p(x)$ with such integer that would guarantee all coefficients to be integers. I've tried to look at the coefficient in composition for general polynomials, which I believe should follow this formula: \begin{align} [x^r]p(q(x))=\sum_{k_1+2k_2+\dots+mk_m=r}\sum_{k_0=0}^{n-(k_1+\dots+k_m)}\binom{k_0+k_1+\dots+k_m}{k_0,k_1,\dots,k_m}a_{k_0+k_1+\dots+k_m}\left(\prod_{j=0}^{m}b_j^{k_j}\right) \end{align} (here a_i and b_i are the coefficients of $p(x)$ and $q(x)$ with degrees n and m, respectively). However it is not at all clear on which coefficient to focus to prove it will give the non-integer number. This arose when trying to solve the Infinitely many solutions leads to existence of a polynomial, but it seems interesting enough by itself.

Is Gromov's conjecture about optimal Betti number estimate true for compact manifolds?

Gromov's conjecture state that: Conjecture: Any complete manifold (M, g) with $\sec\geq 0$ and for any field $\Bbb F$ of coefficients satisfies $$\sum_{i=0}^n b_i(M,\Bbb F)\leq 2^n.$$ Is Gromov's conjecture true for compact non-negatively curved manifolds?

Is it true that $\sum_{i=1}^n (nGx_i^{G} + G^{x_i}) \ge n^2G + G^2n$, for all $x_i>0$, where $G=\prod_{j=1}^nx_j$?

Source: https://math.stackexchange.com/questions/3688041/sum-i-1n-ngx-ig-gx-i-ge-n2g-g2n-for-all-x-i0-where-g Prove or disprove that, for all $x_1,x_2,\ldots,x_n>0$, it holds that $$\sum_{i=1}^n (nGx_i^{G} + G^{x_i}) \ge n^2G + G^2n, \space \space \space \text{where} \space \space \space G=\prod_{j=1}^nx_j.$$ The case $n=2$ is equlvalent to $$2\sqrt{xy}\left(x^{\sqrt{xy}}+y^{\sqrt{xy}}\right)+\left(\sqrt{xy}^{x}+\sqrt{xy}^y\right)\geq 4\sqrt{xy}+2xy\,.$$ We will show that the inequality above is true at least when $xy\geq 1$. By AM-GM, $$x^{\sqrt{xy}}+y^{\sqrt{xy}}\geq 2\,\sqrt{x^{\sqrt{xy}}y^{\sqrt{xy}}}=2\,\sqrt{xy}^{\sqrt{xy}}\geq 2\,\sqrt{xy}\,.$$ Also by AM-GM, $$\sqrt{xy}^x+\sqrt{xy}^y\geq 2\,\sqrt{\sqrt{xy}^x\sqrt{xy}^y}=2\,\sqrt{xy}^{\frac{x+y}{2}}\geq 2\,\sqrt{xy}^{\sqrt{xy}}\geq 2\,\sqrt{xy}\,.$$ Thus, $$\begin{align}2\sqrt{xy}\left(x^{\sqrt{xy}}+y^{\sqrt{xy}}\right)+\left(\sqrt{xy}^{x}+\sqrt{xy}^y\right)&\geq 2\sqrt{xy}(2\sqrt{xy})+(2\sqrt{xy})\\&=4xy+2\sqrt{xy}\geq 4\sqrt{xy}+2xy\,.\end{align}$$

Van der Pol's identity for the sum of divisors and a quartic polynomial equation for odd perfect numbers

In Touchard (1953) it is mentioned that the sum of divisors $\sigma(n)$ satisfies the following recurrence relation ($n>1$): $$n^2(n-1) = \frac{6}{\sigma(n)} \sum_{k=1}^{n-1}(3n^2-10k^2)\sigma(k)\sigma(n-k)$$ Substituting in this equation an odd perfect number $n = \sigma(n)/2$ we find that it is a root of the quartic polynomial: $$ \begin{align} f(x) &= x^4-x^3+12a_0x^2-60a_1x+60a_2 \\ &= (x^3+(n-1)x^2+(12a_0+n^2-n)x+12a_0n+n^3-n^2-60a_1)(x-n) \end{align} $$ where $$a_i = \sum_{k=1}^{\frac{n-1}{2}}k^i \sigma(k)\sigma(n-k),\text{ } i=0,1,2$$ We have: $$n^3(n-1) = 3 \sum_{k=1}^{n-1} (3n^2-10k^2)\sigma(k) \sigma(n-k)$$ and by symmetry of $\sigma(k)\sigma(n-k)$ in $k,n-k$ we get: $$= 3 \sum_{k=1}^{(n-1)/2} (6n^2-10k^2-10(n-k)^2)\sigma(k) \sigma(n-k)$$ which might be simplified to: $$=-12n^2a_0 -60a_2+60na_1$$ which proves that the odd perfect number n is a root of the polynomial $f(x)$ above. However, computations with Sagemath (it takes a few seconds to do the computation) seem to suggest, that for an odd number m, we have $$f(m) > 0, \text{for } m>1 \text{ odd}$$ This observation would maybe prove, that there are no odd perfect numbers. I am aware that $\sigma(k)\sigma(n-k)$ is kind of like a black box to handle, but it would be nice, if maybe for some special cases where m is odd the last inequality could be proven. It might be noticed that it seems like for $n>1$, odd the polynomial $f(x)$ is irreducible over the rational numbers. Here are the first polynomials: n, f(n,t), f(n,n)>0? 3 t^4 - t^3 + 36*t^2 - 180*t + 180 f(n,n)>0 ? True 5 t^4 - t^3 + 228*t^2 - 1860*t + 3300 f(n,n)>0 ? True 7 t^4 - t^3 + 696*t^2 - 7920*t + 20160 f(n,n)>0 ? True 9 t^4 - t^3 + 1548*t^2 - 22500*t + 72900 f(n,n)>0 ? True 11 t^4 - t^3 + 2940*t^2 - 51600*t + 204600 f(n,n)>0 ? True 13 t^4 - t^3 + 4956*t^2 - 102360*t + 478920 f(n,n)>0 ? True 15 t^4 - t^3 + 7752*t^2 - 185760*t + 1004400 f(n,n)>0 ? True 17 t^4 - t^3 + 11376*t^2 - 307620*t + 1900260 f(n,n)>0 ? True 19 t^4 - t^3 + 16020*t^2 - 481980*t + 3309420 f(n,n)>0 ? True 21 t^4 - t^3 + 22080*t^2 - 735120*t + 5559120 f(n,n)>0 ? True Is there a irreducibility criterion which might be applied to all ($n=3,\ldots,21$) of these example polynomials? Thanks for your help! (Originally asked on MO: https://mathoverflow.net/questions/372476/van-der-pols-identity-for-the-sum-of-divisors-and-a-quartic-polynomial-equation) Edit: The odd perfect number is also a root of the polynomial: $$g(x) = x^4-x^3-9A_0x^2+30A_2$$ where $$A_i = \sum_{k=1}^{n-1}k^i \sigma(k)\sigma(n-k),i=0,2$$ But numerical computations suggest, that: $$\gcd(f(x),g(x))=1$$ which would lead to a contradiction. Can this last claim about the $\gcd$ be proven? An answer to the question: It would be nice if someone can spot the error in this answer, otherwise it would follow that there are no odd perfect numbers...: Let $$A_i =

\sum_{k=1}^{n-1} k^i \sigma(k)\sigma(n-k),\text{ } i=0,1,2,3$$. Using the symmetry of $\sigma(k)\sigma(n-k)$ in n,k for A_i we get: $$A_0 = 2a_0$$ $$A_1 = na_0$$ $$A_2 = a_0n^2-2a_1n+2a_2$$ $$A_3 = n^3a_0-3n^2a_1+3na_2$$ On the other hand we can evaluate A_i with Eisenstein series (https://mathoverflow.net/questions/372766/is-there-a-similar-formula-like-ramanunjans-eisenstein-series-identity-for-su): $$A_0 = \tfrac5{12}\sigma_3(n)-\tfrac12n\sigma(n)+\tfrac{\sigma(n)}{12} = \tfrac5{12}\sigma_3(n)-\tfrac12n \cdot 2n +\tfrac{2n}{12}$$ $$A_1 = \frac{5n}{24}\sigma_3(n) - \frac{6n^2-n}{24}\sigma(n) = \frac{5n}{24}\sigma_3(n) - \frac{6n^2-n}{24}2n$$ $$A_2 = \frac{n^2}{8}\sigma_3(n) - \frac{4n^3-n^2}{24}\sigma(n) = \frac{n^2}{8}\sigma_3(n) - \frac{4n^3-n^2}{24}2n$$ $$A_3 = \frac{n^3}{12}\sigma_3(n) - \frac{3n^4-n^3}{24}\sigma(n) = \frac{n^3}{12}\sigma_3(n) - \frac{3n^4-n^3}{24}2n$$ We can solve the set of equations in a_i,A_i for a_i and get: $$a_0 = 1/2 A_0$$ $$a_2=\frac{A_{2}-nA_1}{2} +na_1$$ We can further substitute for A_i the last equations in $\sigma_3(n)$ and then substitute these a_i in $f(x)$. We get (here are the calculations done with Sagemath, I hope there is no bug in this): $$0 = f(n) = n^4 + 6A_0n^2 - n^3 + 30A_1n + 30A_2 $$ $$ = -5/2(12n^2 - 5\sigma_3(n) - 2n)n^2$$ Hence: $$0 = 12 \, n^{2} - 2 \, n - 5 \, \sigma_{3}(n)$$ But $\sigma_3(n)>n^3+1$ and we get the contradiction for $n>1$: $$5(n^3+1) < 5 \sigma_3(n)= 12n^2-2n < 5(n^3+1) $$

Nice lemma regarding factorials and quadratic residues

IMPORTANT: I posted this as I thought I found a generalized result, which turned out to be false (by a trivial flaw), but a nice lemma still remains (however, this can be closed now) Lemma: If $p\equiv 1\pmod{8}$, then $$\bigg(\frac{(\frac{p-1}{4})!}{p}\bigg)=-1$$ This problem below appeared in a USA contest (I think) some time ago: Let p be a prime number and $k\in\mathbb{N}$ such that $p=8k+1$. Suppose that $$\binom{4k}{k}\equiv r\pmod{p}$$ Prove that $\sqrt{r}$ is not an integer. Now this is actually true (By the way, try the problem yourself, it is very beautiful). So under this assumptioin, lets prove the lemma Proof: When $v_2(p-1)=3$ This gives us $p\equiv 9\pmod{16}\Rightarrow p\equiv 1\pmod{8}$. Lets write $p=8k+1$. So by the above problem i just stated, we get: $$\bigg(\frac{\binom{4k}{k}}{p}\bigg)=-1$$ Lets start interpreting this: $$\bigg(\frac{\binom{4k}{k}}{p}\bigg)=-1\Leftrightarrow \bigg(\frac{(4k)!}{p}\bigg)=-\bigg(\frac{\frac{1}{k!\cdot(3k)!}}{p}\bigg)$$ Notice that $$1 =\bigg(\frac{1}{p}\bigg)=\bigg(\frac{\frac{1}{k!\cdot(3k)!}}{p}\bigg)\cdot\bigg(\frac{k!\cdot(3k)!}{p}\bigg)$$ so $$\bigg(\frac{k!\cdot(3k)!}{p}\bigg)=\frac{1}{\bigg(\frac{\frac{1}{k!\cdot(3k)!}}{p}\bigg)}=\bigg(\frac{\frac{1}{k!\cdot(3k)!}}{p}\bigg)$$ Thus, substituting in $$\bigg(\frac{(4k)!}{p}\bigg)=-\bigg(\frac{\frac{1}{k!\cdot(3k)!}}{p}\bigg)$$ we have $$\bigg(\frac{(4k)!}{p}\bigg)=-\bigg(\frac{k!\cdot(3k)!}{p}\bigg)\Leftrightarrow\bigg(\frac{(3k)!}{p}\bigg)\cdot\bigg(\frac{(3k+1)(3k+2)...4k}{p}\bigg)=-\bigg(\frac{(3k)!}{p}\bigg)\cdot\bigg(\frac{k!}{p}\bigg)$$ so we get $$\bigg(\frac{(3k+1)(3k+2)...4k}{p}\bigg)=-\bigg(\frac{k!}{p}\bigg)$$ which is equivalent to $$\big((3k+1)(3k+2)...4k\big)^{\frac{p-1}{2}}\equiv-\big(k!\big)^{\frac{p-1}{2}}\pmod{p}$$ Multiplying both sides by $2^{\frac{p-1}{2}}$, we have: $$\big((6k+2)(6k+4)...8k\big)^{\frac{p-1}{2}}\equiv-\big(2\cdot4\cdot6...\cdot2k\big)^{\frac{p-1}{2}}\pmod{p}$$ But $$\big((6k+2)(6k+4)...8k\big)^{\frac{p-1}{2}}\equiv\big(-(2k-1)\cdot-(2k-3)...\cdot-1\big)^{\frac{p-1}{2}}\equiv \big((-1)^k\cdot1\cdot3...\cdot(2k-1)\big)^{\frac{p-1}{2}}\pmod{p}$$ $\frac{p-1}{2}=4k$, so $$\big((-1)^k\cdot1\cdot3...\cdot(2k-1)\big)^{\frac{p-1}{2}}\equiv\big(1\cdot3...\cdot(2k-1)\big)^{\frac{p-1}{2}}\pmod{p}$$ Substituting in $$\big((6k+2)(6k+4)...8k\big)^{\frac{p-1}{2}}\equiv-\big(2\cdot4\cdot6...\cdot2k\big)^{\frac{p-1}{2}}\pmod{p}$$ we get the following: $$\big(1\cdot3...\cdot(2k-1)\big)^{\frac{p-1}{2}}\equiv-\big(2\cdot4\cdot6...\cdot2k\big)^{\frac{p-1}{2}}\pmod{p}$$ Finally, by multiplying both sides by $\big(2\cdot4\cdot6...\cdot2k\big)^{\frac{p-1}{2}}$, we get: $$(2k)!\equiv-1\big(2\cdot4\cdot6...\cdot2k\big)^{p-1}\equiv-1\pmod{p}$$ So we have $$\bigg(\frac{(\frac{p-1}{4})!}{p}\bigg)=\bigg(\frac{(2k)!}{p}\bigg)=-1$$ Which is exactly what we wanted to prove. Thank you!

Given $A\subset \mathbb{N}$, probability of a $B\subset A$, $s(B)\in\mathbb{P}$

To clarify the notation, for a finite set K, let $s(K)$ be the sum of the elements of K. My question Quite straight forward, I want to ask this: Given $A\subset\mathbb{N}$ such that A is finite, what the the probability that there exists $B\subset A$ such that $s(B)$ is a prime number. Motivation This is mainly inspired by the fact that the probability of a number, N, being a prime is $\sim\frac{1}{\log{N}}$ and the fact that in a recent post, I talked about the probability of the sum of n randomly chosen integers being divisible by p, a prime (which was later on generalized). To be honest, I have almost no knowledge in probability or advanced number theory whatsoever, so the inly background I can provide you with is this idea I got: When I first thought of the probability of a number being a prime, I had this train of thought (more or less, this is a summary): So i have $\pi(n)$ favorable cases and n total cases, as n goes to infinity, so the probability would be: $$\lim_{n\to\infty}\frac{\pi(n)}{n}=\lim_{n\to\infty}\frac{1}{\log{n}}$$ But that gives us 0, which is a contradiction. So then I thought of something very similar but simpler: instead of having $\pi(m)$ favorable cases and m total cases as m gets arbitrarely big, we can just have n favorable cases and p_n total cases, because $n\leq p_n$. So the probability now is $$\sim\frac{n}{p_n}\sim\frac{n}{n\log{n}}=\frac{1}{\log{n}}$$ But after doing this, I thought I could use an almost identical approach to see what is the probability for a number n such that $n+c$ is a prime (for a given constant c), but I am not sure this actually works. However, I am not sure how to generalize this to sums or sets. To sum up, I would appreciate any help or ideas. Thank you for reading.

Carmichael number divisible by a given positive integer

Prove or disprove this conjecture : If $k>2$ is an integer with $\gcd(k,\varphi(k))=1$, then there is a Carmichael number N with $k\mid N$ The condition $\gcd(k,\varphi(k))=1$ is necessary. Otherwise, k would not be squarefree and therefore also N , which is impossible. Or there would be prime factors p,q of k and therefore N, with $p\mid q-1$. This is also impossible since this would imply $p\mid N-1$ because of $q-1\mid N-1$ contradicting $p\mid N$ But is it also sufficient ? And if yes, is there an efficient method to construct a Carmichael number divisible by k ? A particular hard case seems to be $k=885=3\cdot 5\cdot 59$. Is there a Carmichael number divisble by 885 ?

Conjecture regarding trapping rational numbers in some special intervals

Conjecture: Let $b\in\mathbb{N}_{\geq3}$ and $\{x_i\}$ be a collection of $b-2$ rational numbers greater than 1. Does there always exist a natural number a such that for all i there exists some natural number $1\leq c\leq a$ such that: $$\displaystyle \frac{ab-1}{(c-1)b+1}\geq x_i \geq \frac{ab-1}{cb-1}\tag{1}$$ One may think of this as having a UNION of a intervals $\left[\frac{ab-1}{cb-1},\frac{ab-1}{(c-1)b+1}\right]$ on the real line and proving that, for some a, these can trap any finite discrete set of rational numbers having cardinality $b-2$. For example, Let's assume $b=10$, $x=\{\frac{12}{5},\frac{17}{5},\frac{59}{10},\frac{187}{20},15,21,\frac{67}{2},39 \}$, then (1) is true for $a=4$ and $a=5$ and therefore the intervals for $a=4,5$ contain or "trap" all the members of set x. In the diagram, the red/green regions are intervals $\left[\frac{ab-1}{cb-1},\frac{ab-1}{(c-1)b+1}\right]$ for all $c<a$. What mathematical tools can one employ to tackle this? WHAT I DID: I solved the inequality (1) for a and got $$\large x_i\left(1-\frac{2}{b}\right)+\frac{x_i+1}{b}+cx_i\geq a\geq \frac{x_i+1}{b}+cx_i\tag{2}$$ Note that $\frac{x_i+1}{b}+cx_i$ is common on both sides of the inequality. Now I'll just have to plug in the values of x_i to get $b-2$ inequalities and check for a common value of a for any c. For example, Let $x_i \in \{ \frac{101}{4},\frac{3001}{7} \}$ and $b=4$ then we have inequalities $\frac{307}{16}+\left(\frac{101}{4}\right)c_1\geq a\geq \frac{105}{16}+\left(\frac{101}{4}\right)c_1$ $\frac{911}{32}+\left(\frac{301}{8}\right)c_2\geq a\geq \frac{309}{32}+\left(\frac{301}{8}\right)c_2$ Put $c=2$ in the first inequality and $c=1$ in the second inequality to get a common $a=58$. But how should one go about to prove that there will always be some value of a which satisfies the above set of inequalities? I calculated numerically for some random b and x_i and always managed to get some a, i.e., there existed some a which trapped random x_i given some random b. A counterexample may prove the negative but I was unable to find any.

Is this proof regarding odd perfect numbers valid?

(Edited in response to a comment.) Here are my: QUESTIONS (1) Is this proof regarding odd perfect numbers valid, particularly the part where it says $$\dfrac{2n^2}{D(n^2)} \neq (q + 1)?$$ (2) If the proof is incorrect, how can the argument be mended to produce a valid proof? Let $N = q^k n^2$ be an odd perfect number with special/Euler prime q. (That is, $\gcd(q,n)=1$ and $q \equiv k \equiv 1 \pmod 4$.) Let $\sigma(x)$ denote the sum of the divisors of $x \in \mathbb{N}$. Define $$D(n^2) := 2n^2 - \sigma(n^2)$$ to be the deficiency of the non-Euler part n^2. Define $$I(n^2) := \dfrac{\sigma(n^2)}{n^2}$$ to be the abundancy index of n^2. Since N is perfect, then we have $$\sigma(q^k)\sigma(n^2)=\sigma(q^k n^2)=\sigma(N)=2N=2q^k n^2$$ from which it follows that $$I(N)=2 \iff I(q^k)I(n^2)=2.$$ But since q is prime, $I(q^k)$ can be rewritten as $$I(q^k) = \dfrac{q^{k+1} - 1}{q^k (q - 1)}$$ which can be bounded as follows (since $k \equiv 1 \pmod 4$ implies that $k \geq 1$) $$\frac{q+1}{q} = I(q) \leq I(q^k) < \dfrac{q^{k+1}}{q^k (q - 1)} = \frac{q}{q - 1}.$$ This implies that $$\dfrac{2(q - 1)}{q} < I(n^2) = \dfrac{2}{I(q^k)} \leq \dfrac{2q}{q + 1}$$ from which it follows that $$\dfrac{2}{q+1} \leq 2 - I(n^2) = \dfrac{D(n^2)}{n^2} < \dfrac{2}{q},$$ which means that $$q < \dfrac{2n^2}{D(n^2)} \leq (q + 1).$$ Since $2n^2$ is even and $D(n^2) = 2n^2 - \sigma(n^2)$ is always odd (since n^2 is a square), then $$\dfrac{2n^2}{D(n^2)}$$ cannot be an integer. This implies that $$\dfrac{2n^2}{D(n^2)} \neq (q + 1)$$ which implies that $$\dfrac{n^2}{D(n^2)} \neq \dfrac{q+1}{2}$$ and $$2 - I(n^2) = \dfrac{D(n^2)}{n^2} \neq \dfrac{2}{q+1}.$$ Finally, we obtain $$I(n^2) \neq \bigg(2 - \dfrac{2}{q+1}\bigg) = \dfrac{2q}{q+1}$$ which implies that $$I(q^k) = \dfrac{2}{I(n^2)} \neq \dfrac{q+1}{q},$$ thus resulting in $$k \neq 1.$$

Sketch of proof concerning a conjecture of Vasile Cirtoaje : $(1-x)^{(2x)^k}+x^{(2(1-x))^k}\leq 1$ with $k\geq1$ and $0<x\leq \frac{1}{2}$

Claim Prove that [1]: Let $0<x\leq 0.5$ and $k\geq 1$ a real number then we have : $$h(k)=(1-x)^{(2x)^k}+x^{(2(1-x))^k}\leq 1$$ Sketch of proof : The case $k\geq 1+\alpha$: We define α as : $$\lim_{x\to 0.5^-}=\frac{\ln\Big(2(2^{2x}x^2(1-x)2)\Big)}{\ln(2x)}=\frac{\ln\Big(2(1-(2^{2x}x^2(1-x)2))\Big)}{\ln(2(1-x))}=\alpha=1.69315\cdots$$ We have : $$x^{2(1-x)}\leq2^{2x}(1-x)2x^2$$ And : $$(1-x)^{2x}\leq 1-2^{2x}(1-x)2x^2$$ For a sketch of proof see Refinements of the inequality $f(x)=x^{2(1-x)}+(1-x)^{2x}\leq 1$ for $0<x<0.5$ So we have : $$x^{(2(1-x))^k}\leq f(x)^{(2(1-x))^{k-1}}=(2^{2x}(1-x)2x^2)^{(2(1-x))^{k-1}}$$ And : $$(1-x)^{(2x)^k}\leq (1-2^{2x}(1-x)2x^2)^{(2x)^{k-1}}$$ Now we want $y\geq 1$ a real number : $$(2x)^{k-1}\geq (2f(x))^{y}$$ And $$(2(1-x))^{k-1}\geq (2(1-f(x)))^{y}$$ Solving this we have $$\frac{\ln\Big(2(1-(2^{2x}x^2(1-x)2))\Big)}{\ln(2(1-x))}\leq \frac{k-1}{y}\leq \frac{\ln\Big(2(2^{2x}x^2(1-x)2)\Big)}{\ln(2x)}\quad (1)$$ The constraint (1) is honoured if :$$\alpha=\frac{k-1}{y}$$ So we have : $$x^{(2(1-x))^k}\leq

(f(x))^{(2(1-f(x))^{\frac{k-1}{\alpha}} }\quad (2)$$ And : $$(1-x)^{(2x)^k}\leq (1-f(x))^{(2f(x))^{\frac{k-1}{\alpha}}}\quad (3)$$ Adding (2) and (3) we have : $$h(k)\leq (1-f(x))^{(2f(x))^{\frac{k-1}{\alpha}}}+(f(x))^{(2(1-f(x))^{\frac{k-1}{\alpha}}}$$ We can repeat the reasoning p times ($p\geq 1$ a natural number) and the last exponent becomes : $$1\leq \frac{k-1}{\alpha^p}\leq \alpha$$ It's true because we can always choose k such that : $$\alpha^p\leq k \leq \alpha^{p+1}$$ So we reduce this case to the case $1\leq k\leq 1+\alpha $ Case $k\leq 1+\alpha $ Using Bernoulli's inequality and derivatives we have $1\leq k\leq 2$ and $0<x\leq \frac{1}{4}$ $$(1-x)^{(2x)^k}\leq 1-x(2x)^k$$ And $$x^{(2(1-x))^k}\leq x(2x)^k$$ In the same idea we have $2\leq k\leq 1+\alpha$ and $0<x\leq \frac{1}{3}$ $$(1-x)^{(2x)^k}\leq 1-x(2x)^k$$ And $$x^{(2(1-x))^k}\leq x(2x)^k$$ Now to finalize the sketch of proof we have : $h(k)$ is decreasing for $1\leq k\leq 2$ and $ \frac{1}{4}\leq x\leq 0.5\quad (4)$ $h(k)$ is decreasing for $2\leq k\leq 1+\alpha$ and $ \frac{1}{3}\leq x\leq 0.5\quad (5)$ Questions : It is good and coherent ? How to show (4) and (5)? Thanks in advance ! Regards Max [1] Vasile Cirtoaje, "Proofs of three open inequalities with power-exponential functions", The Journal of Nonlinear Sciences and its Applications (2011), Volume: 4, Issue: 2, page 130-137. https://eudml.org/doc/223938 https://link.springer.com/article/10.1186/1029-242X-2013-468

Two homotopy equivalent closed n-manifolds are homeomorphic

I heard somewhere that there is a wrong conjecture that states: Two homotopy equivalent closed n-manifolds ($n\geq 3$) are homeomorphic. and the lens spaces are the first counterexample to this conjecture. I want to know the author of this wrong conjecture, and a reference for it. I am also curious about other counterexamples? (Here is a related question)

Is $X = (n-1)^n + n$ always composite for $n \geq 4 \in \Bbb Z$?

$$\textit{Proposition}: \text{Given} \ X = (n-1)^n + n,\ \forall \ n \in \Bbb Z, \ n \geq 4, X \ \text{is composite.}$$ This came up sort of at random on a mailing list and it's jammed its way into being stuck in my brain. It's easy to test that it's true for the first few hundred thousand integers, suggesting it's likely true. There are a few things that are easy to prove: X is always odd: if $(n-1)^n$ is odd, n is even and vice versa. $(n - 1) \equiv -1 \pmod n $. Since $n \equiv 0 \pmod n$, we can see that $X \equiv (-1)^n \pmod n $. Therefore, $X \equiv -1 \pmod n$ for odd n, and $X \equiv 1 \pmod n $ for even n. If $n \equiv 2 \pmod 3$, then $n-1 \equiv 1 \pmod 3$, so $(n-1)^n \equiv 1 \pmod 3$. If we add $n \equiv 2 \pmod 3$, we have $0 \pmod 3$, so $3 \mid X$. So a third of possible values for n are easily shown to be composite, namely $n = 3m + 2$. If $n \equiv \{4,13\} \pmod {20}$, then $5 \mid X$, as follows: If $n \equiv 4 \pmod {20}$, then $4 \mid n$, $n \equiv 4 \pmod{10}$, and $(n - 1) \equiv 3 \pmod{10}$. Then we have $4^3+4 \equiv 5 \pmod{10}$ If $n \equiv 13 \pmod {20}$, then $4 \mid (n-1)$, $(n-1) \equiv 12 \pmod{20}$, and $(n-1) \equiv 2 \pmod {10}$. Additionally, $n \equiv 1 \pmod 4$ and $n \equiv 3 \pmod{10}$. Therefore, in decimal, $(10k + 2)^{4m+1} \equiv 2 \pmod{10}$. Adding $n \equiv 3 \pmod{10}$ gives $X \equiv 5 \pmod{10}$. That takes care of 40% of the integers. But (1) I feel like we ought not to have to go through the integers modulus by modulus, and (2) well, we have a lot of integers left. Some other interesting tidbits that may or may not help: For n even and $n \not\equiv 2 \pmod 3$, X is often divisible by $(n+1)$, or by p if $(n+1) = p^2$, p prime. Up to $n = 72$, this fails for $n = 34, 54, 64$. For $n \not\equiv 2 \pmod 3$, X is sometimes divisible by $(2n-1)$. Again up to $n = 72$, this is true for even $n = 6, 10, 22, 30, 34, 42, 54, 66, 70$. (Interesting, for all of those, $n \equiv 2 \pmod 4$. Just noticing that.) It's true for odd $n = 9, 21, 37, 45, 49, 57$... which are all $n \equiv 1 \pmod 4$. Of course, being sometimes divisible by those numbers doesn't tell us why they're divisible by them. I tried using partial binomial expansions (learning about Stirling numbers along the way) but couldn't get anything useful. Has anyone seen or worked with this proposition before? Is it proven and I just can't find it anywhere?

A new method for finding a solution (when they exist) to $x^2 = a \pmod p$?

For prime $p \ge 2$ define a set $S \subset \Bbb N$ by $\quad S = \{t^2 \mid t \ge 1 \land t^2 \lt p\}$ Let a be an integer satisfying $\quad 1 \le a \lt p$ Conjecture: The equation $x^2 \equiv a \pmod p$ has a solution if and only if there exists an integer s belonging to S such that, when applying Euclidean division by setting the dividend to sa and the divisor to p, the remainder also belongs to S. When a solution exists, it can be calculated by solving the corresponding $tx \equiv 1 \pmod{p}$ equation. If this is known please point to some references or supply a proof. Otherwise please help in finding a counter-example; see also Jaap Scherphuis' comments. It is certainly possible that S has to be expanded, up, to say, $\; S = \{t^2 \mid 1 \le t \lt p\}$ when forming the divisor sa, but the 'tighter the better' when formulating algorithms for this idea. But we really want the aesthetically pleasing duality statement, $\quad S^\text{*} (\text{residue side of } sa) = S (\text{multiply side of } sa$). Example 1: $x^2 = 2 \pmod{17}$. Here $S = \{1,4,9,16\}$. Dividing $4 \cdot 2:\quad$ $8 = 0\cdot 17 + 8$ and $8 \notin S$ Dividing $9 \cdot 2:\quad$ $18 = 1\cdot 17 + 1$ and $1 \in S$ We have $[3]^{-1} = [6]$ in the $\text{modulo-}17$ system. So $\; x^2 = 2 \pmod{17} \; \text{ iff } \; 3^2 x^2 \equiv 1 \pmod{17} \; \text{ iff } \; \large x^2 \equiv 3^{-2} \pmod{17} \; \text{ iff } \; x^2 \equiv 6^{2} \pmod{17} $ and we've found a solution, $x = 6$. Example 2: $x^2 \equiv 3\pmod {10007}$. Here is a Python program: S =[1, 4, 9, 16, 25, 36, 49, 64, 81, 100, 121, 144, 169, 196, 225, 256, 289, 324, 361, 400, 441, 484, 529, 576, 625, 676, 729, 784, 841, 900, 961, 1024, 1089, 1156, 1225, 1296, 1369, 1444, 1521, 1600, 1681, 1764, 1849, 1936, 2025, 2116, 2209, 2304, 2401, 2500, 2601, 2704, 2809, 2916, 3025, 3136, 3249, 3364, 3481, 3600, 3721, 3844, 3969, 4096, 4225, 4356, 4489, 4624, 4761, 4900, 5041, 5184, 5329, 5476, 5625, 5776, 5929, 6084, 6241, 6400, 6561, 6724, 6889, 7056, 7225, 7396, 7569, 7744, 7921, 8100, 8281, 8464, 8649, 8836, 9025, 9216, 9409, 9604, 9801, 10000] for m in S: r = m*3 % 10007 if r in S: print(m, m**.5, r) raise SystemExit with output $3721\; 61.0\; 1156$ We have $1156 = 34^2$. We

have $[61]^{-1} = [3281]$ in the $\text{modulo-}10007$ system. So $\; x^2 = 3 \pmod{10007} \; \text{ iff } \; 61^2 x^2 \equiv 34^2 \pmod{10007} \; \text{ iff } \; \large x^2 \equiv 61^{-2} 34^2 \pmod{10007} \; \text{ iff } \; x^2 \equiv (3281 \cdot 34)^2 \pmod{10007} \; \text{ iff } \; x^2 \equiv 1477^2 \pmod{10007}$ and we've found a solution, $x = 1477$. Example 3: $x^2 \equiv 3 \pmod{7}$. Here $S = \{1,4\}$. Since $4 \times 3 \equiv 5 \pmod{7}$ is not in S, there are no solutions. Example 4: $x^2 = 19 \pmod{127}$ $\; x^2 \equiv 19 \pmod{127} \; \text{ iff }$ $\;6^2 x^2 \equiv 6^2 \cdot 19 \pmod{127}\; \text{ iff }$ $\;6^2 x^2 \equiv 7^2 \pmod{127}$ We have $[6]^{-1} = [106]$ in the $\text{modulo-}127$ system. So, $\;x^2 \equiv 6^{-2} 7^2 \pmod{127}\; \text{ iff }$ $\;x^2 \equiv \bigr(6^{-1} 7^1 \bigr)^2 \pmod{127}\; \text{ iff }$ $\;x^2 \equiv \bigr(106 \cdot 7 \bigr)^2 \pmod{127}\; \text{ iff }$ $\;x^2 \equiv 107^2 \pmod{127}$ and we see that $x \equiv 107 \pmod{127}$ is a solution. My Work After seeing lonza leggiera's counter-example answer to my question here, I went back to the drawing board and this kind of just 'popped out'. In this question I wanted to focus on the extensively studied modulo prime systems, but if it works here further research would be warranted.

On the nearest-square function - Part 2 and the quantity $m^2 - p^k$ where $p^k m^2$ is an odd perfect number

(Note: This question has been cross-posted to MO.) This question is an offshoot of this earlier one and this other question. Let $n = p^k m^2$ be an odd perfect number with special prime p satisfying $p \equiv k \equiv 1 \pmod 4$ and $\gcd(p,m)=1$. It was conjectured in Dris (2008) and Dris (2012) that the inequality $p^k < m$ holds. Brown (2016) showed that the Dris Conjecture (that $p^k < m$) holds in many cases. It is trivial to show that $m^2 - p^k \equiv 0 \pmod 4$. This means that $m^2 - p^k = 4z$, where it is known that $4z \geq {10}^{375}$. (See this MSE question and answer, where the case $m < p^k$ is considered.) Note that if $p^k < m$, then $$m^2 - p^k > m^2 - m = m(m - 1),$$ and that $${10}^{1500} < n = p^k m^2 < m^3$$ where the lower bound for the magnitude of the odd perfect number n is due to Ochem and Rao (2012). This results in a larger lower bound for $m^2 - p^k$. Therefore, unconditionally, we have $$m^2 - p^k \geq {10}^{375}.$$ We now endeavor to disprove the Dris Conjecture. Consider the following sample proof argument: Theorem If $n = p^k m^2$ is an odd perfect number satisfying $m^2 - p^k = 8$, then $m < p^k$. Proof Let $p^k m^2$ be an odd perfect number satisfying $m^2 - p^k = 8$. Then $$(m + 3)(m - 3) = m^2 - 9 = p^k - 1.$$ This implies that $(m + 3) \mid (p^k - 1)$, from which it follows that $$m < m + 3 \leq p^k - 1 < p^k.$$ We therefore conclude that $m < p^k$. QED So now consider the equation $m^2 - p^k = 4z$. Following our proof strategy, and the formula in the accepted answer to the first hyperlinked question, we have: $$m^2 - \bigg(\lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\bigg)^2 = p^k + \Bigg(4z - \bigg(\lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\bigg)^2\Bigg).$$ So the only remaining question now is whether it could be proved that $$\Bigg(4z - \bigg(\lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\bigg)^2\Bigg) = -y < 0$$ for some positive integer y? In other words, is it possible to prove that it is always the case that $$\Bigg((m^2 - p^k) - \bigg(\lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\bigg)^2\Bigg) < 0,$$ if $n = p^k m^2$ is an odd perfect number with special prime p? (Additionally, note that it is known that $m^2 - p^k$ is not a square, if $p^k m^2$ is an OPN with special prime p. See this MSE question and the answer contained therein.) If so, it would follow that $$\Bigg(m + \lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\Bigg)\Bigg(m - \lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\Bigg) = p^k - y$$ which would imply that $$\Bigg(m + \lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\Bigg) \mid (p^k - y)$$ from which it follows that $$m < \Bigg(m + \lfloor{\sqrt{m^2 - p^k} + \frac{1}{2}}\rfloor\Bigg) \leq p^k - y < p^k.$$ Update (November 11, 2020 - 10:21 PM Manila time) Please check out the recently posted answer for a minor adjustment to the logic that should make the general proof argument work.

Conjecture about :$\frac{a}{\sqrt[4]{8(b^4+c^4)}}+\frac{b}{a+c}+\frac{c}{a+b}\geq\sqrt{\frac94+\frac32 \cdot \frac{(a-b)^2}{ab+bc+ca}}$

It's a conjecture . I combine two inequalities : Stronger than Nesbitt inequality and Stronger than Nesbitt's inequality $\frac{a}{\sqrt[4]{8(b^4+c^4)}}+\frac{b}{a+c}+\frac{c}{a+b}\geq\frac{3}{2}$ So now the conjecture : Let $a,b,c>0$ such that $a\geq b \geq c$ then we have : $$\frac{a}{\sqrt[4]{8(b^4+c^4)}}+\frac{b}{a+c}+\frac{c}{a+b}\geq\sqrt{\frac94+\frac32 \cdot \frac{(a-b)^2}{ab+bc+ca}}$$ I cannot find any counter-example until now . To prove it I have tried the same method as here Prove this refinement of Nesbitt's inequality based on another without success . My question : Have you an element of proof or an counter-example ? Thanks in advance !! Max .

Can the Infinite Product $\prod_{n=1}^\infty \frac{a_n}{a_n + 1}$ Converge or Diverge to Zero?

Can the infinite product $\prod_{n=1}^\infty \frac{a_n}{a_n + 1}$ converge or diverge to zero when the sequence a_n is monotonically increasing? I conjecture that this is impossible given that $\lim_{n\to\infty}\frac{a_n}{a_n+1}$ by the monotonic increase of the a_n. However, I don't know of a rigorous proof or disproof of this, and analyzing convergence of infinite series and infinite products is not something I am very familiar with. If someone could provide a proof or disproof of this conjecture (preferably with a reference to a known theorem), or explain what additional restrictions need to be imposed on a_n for the conjecture to hold, I would be very appreciative!

Integrate $\int_0^1 \Bigl(\mathrm{Li}_2\bigl(\frac{x-1}{x}\bigr)\Bigr)^2 \mathrm{d}x$

This question has some relationship to this integral: Let Li_2 be the dilogarithm. Then, numerically, $$ \int_0^1 \Bigl(\mathrm{Li}_2\bigl(\frac{x-1}{x}\bigr)\Bigr)^2 \mathrm{d}x = \frac{17}{180}\pi^4, $$ as can be checked by Mathematica code like NIntegrate[PolyLog[2, (x-1)/x]^2, {x,0,1}, WorkingPrecision -> 100] and N[17/180 * Pi^4, 100] both of which output the same digits 9.19974748654467462788603142059992717358538 3 ... Is this a known identity? Some related results appear in Freitas and Laurenzi, but without this specific argument in the dilogarithm.

Conjecture: $a^{(2(1-a))^{\frac{1}{n}}}+b^{(2(1-b))^{\frac{1}{n}}}+c^{(2(1-c))^{\frac{1}{n}}}+\frac{c}{n}\leq 1$

Hi it's a conjecture inspired by a work of Vasile Cirtoaje : Claim : Let $0.5\geq a \geq b \geq c\geq 0$ such that $a+b+c=1$ and $n\geq 1$ a natural number then we have : $$a^{(2(1-a))^{\frac{1}{n}}}+b^{(2(1-b))^{\frac{1}{n}}}+c^{(2(1-c))^{\frac{1}{n}}}+\frac{c}{n}\leq 1$$ To prove it I have tried Bernoulli's inequality as we have : $$a^{(2(1-a))^{\frac{1}{n}}}\leq 1-(1-a)(2(1-a))^{\frac{1}{n}}$$ But it's not enough and wrong. I have tested for $n=1,2,3,4,5$.Moreover the equality case is $a=b=0.5$. Case $n=1$: As in my previous posts we have the inequality $x\in[0,0.5]$: $$x^{2(1-x)}\leq 2^{2x+1}x^2(1-x)$$ applying this for each variable we want to show : $$2^{2a+1}a^2(1-a)+2^{2b+1}b^2(1-b)+2^{2(1-(a+b))+1}(1-(a+b))^2(a+b)+1-(a+b)\leq 1$$ Now by Bernoulli's inequality we have: $$2^{2x+1}\leq 2(1+2x)$$ Remains to show : $$2(1+2a)a^2(1-a)+2(1+2b)b^2(1-b)+2(1+2(1-(a+b)))(1-(a+b))^2(a+b)+1-(a+b)\leq 1$$ Wich is wrong because we have an equality case at $b=c=0.25$ and $a=0.5$! My question : Have you a counter-example or later (if it's true) a proof ? Thanks in advance !

Bézout giving some spare coins to Frobenius? (the Coin Problem)

Let a and b be relatively prime positive integers and write the two minimal Bézout's identity pairs, $\tag 1 (s)\,a + (t)\,b = 1$ $\tag 2 (u)\,a + \;(v)\,b = 1$ where the extended Euclidean algorithm produces one of them (see this discussion on the structure of solutions). Set $\quad \; \; x = s - 1$ if $s \gt 0$, else set $x = u-1$ Set $\quad \; \; y = t - 1$ if $t \gt 0$, else set $y = v-1$ Let $n = ab - a - b$ be the solution to the Frobenius coin problem for a and b. Conjecture: The numbers x and y derived from the extended Euclidean algorithm satisfy the equation $n + 1 = (a-1)(b-1) = (x)\,a + (y)\,b$ My Work I noticed this relationship occured while working on this and that (not spelled out in this answer). Here is another example. Let $a = 227$ and $b =2011$ and write $\tag{Z1} (-691)\,227 + (78)\,2011 = 1$ $\tag{Z2} (1320)\,227 + \;(-149)\,2011 = 1$ and $x = 1319$ and $y = 77$. The statement $ (1319)\,227 + \;(77)\,2011 = 227\cdot2011 - 227 - 2011 + 1$ is true. If the conjecture is true one could use the connection to calculate Bézout's coefficients (in the coprime setting) with new algorithms. Example: Use an ad-hoc method (algorithm?) to solve for x and y in the equation $\quad (x)\,227 + \;(y)\,2011 = 227\cdot2011 - 227 - 2011 + 1$ Examining $\quad 227\cdot2011 - 227 - 2011 + 1 = (2011)\, 227 - 2237$ the problem is reduced to solving $\quad 227 k \equiv 2237 \pmod{2011}$ That gives $k \equiv 692 \pmod{2011}$ and $\quad (2011)\, 227 - 2237 =$ $\quad (2011 -692)\, 227 + 692\cdot227 - 2237 =$ $\quad (1319)\, 227 + 154847$ Now use our 'best' algorithm for dividing (exactly) 2011 into 154847, $\quad \large \frac{154847}{2011} = 77$ so $\quad (1319)\, 227 + 154847 =$ $\quad (1319)\, 227 + (77) \, 2011 $ and we can now easily calculate Bézout's coefficients by solving the linear equations $\quad (z)\,227 + (78)\,2011 = 1$ and $\quad (1320)\,227 + (z)\,2011 = 1$

Conjecture : A lower bound for the prime counting function .

Well it take my a little bit of time to find it but now I think that my conjecture is ready . Conjecture : Let $n\geq 100$ and then define the sum : $$S(n)=\sum_{k=1}^{n}\frac{1}{\operatorname{argtanh}\left(\frac{k}{k+1}\right)}$$ Then we have : $$\lceil{S(n)}\rceil\leq 2\pi(n)$$ Where we see the ceiling function and the prime counting function .Nicely the equality case is $n=100$. I have checked my conjecture with wolfram alpha up to $n=1000$ and extra values of n up to $n=1000000$ Obviously I'm inspired by the prime number theorem and it's not a chance if I choose $\operatorname{argtanh}$ in my conjecture . I have several questions: Well first I would like to know if it's true for larger n . Is my conjecture equivalent to other conjecture (stronger or weaker conjecture) . Can we improve the conjecture by adding (by example) a fixed exponent ? What my conjecture involves ? If it's not true for small n can we take a larger n to start with ? Thanks!

Conjecture regarding the sum of prime factors of $x!$ and $(x-1)!$?

I think using dodgy means I can show the following: Let $\lambda(x)$ be the sum of primes in x. For example: $$ \lambda(2) = 2$$ $$ \lambda(4) = 2 + 2 = 4$$ $$ \lambda(6) = 3 + 2 = 5$$ Then for large n: $$ \frac{\lambda (n!)}{\lambda ((n-1)!)} \sim \frac{\ln (n!)}{\ln (n-1)!}$$ Or more precisely substracting 1: $$ \frac{\lambda (n)}{\lambda ((n-1)!)} \sim \frac{\ln (n)}{\ln (n-1)!}$$ Or even better: $$ \frac{\lambda (n)}{\lambda ((n-1)!)} - \frac{\ln (n)}{\ln (n-1)!} = o(1)$$ Can someone prove or disprove this conjecture? For example: $$ \frac{\lambda(8!)}{\lambda(7!)} = \frac{31}{26} \approx 1.23$$ And $$ \frac{\ln(8!)}{\ln(7!)} \approx 1.244 $$ Substracting 1: $$ .23 \approx .24$$

Sums of integer powers similar to Prouhet-Tarry-Escott problem

Recall Prouhet-Tarry-Escott problem. Its solution shows that certain sums of powers of integers can be made to vanish simultaneously if their signs are chosen to follow the Thue-Morse sequence, e.g. $$\sum_{k=0}^{2^4-1}(-1)^{\sigma_2(k)}\,k^n=0\quad\text{for}\;n<4,\quad\text{i.e.}\\ \small \begin{array}{l} 0^1+3^1+5^1+6^1+9^1+10^1+12^1+15^1=1^1+2^1+4^1+7^1+8^1+11^1+13^1+14^1 \\ 0^2+3^2+5^2+6^2+9^2+10^2+12^2+15^2=1^2+2^2+4^2+7^2+8^2+11^2+13^2+14^2 \\ 0^3+3^3+5^3+6^3+9^3+10^3+12^3+15^3=1^3+2^3+4^3+7^3+8^3+11^3+13^3+14^3, \\ \end{array}$$ where $\sigma_2(k)$ is the sum of digits of k in base-2. I am interested in sums of powers of a similar form, but with larger exponents (such that the sum does not vanish anymore). I was able to make a few conjectures: $$\begin{align} &\sum _{k=0}^{2^n-1} (-1)^{\sigma _2(k)}\, k^{n+2}\stackrel{\color{gray}?}{=}\frac{2^{\binom{n}{2}}}{36}\, (-1)^n\, \left(2^n-1\right)\, \left(5\times2^n-4\right)\, (n+2)!\\ \\ &\sum _{k=0}^{2^n-1} (-1)^{\sigma _2(k)}\,k^{n+3}\stackrel{\color{gray}?}{=}\frac{2^{\binom{n}{2}}}{72}\,(-1)^n\,\left(2^n-1\right)^2\,\left(2\times2^n-1\right)\,(n+3)!\\ \\ &\small\sum _{k=0}^{2^n-1} (-1)^{\sigma_2(k)}\,k^{n+4}\stackrel{\color{gray}?}{=}\frac{2^{\binom{n}{2}}}{32400}\,(-1)^n\,\left(2^n-1\right)\,\left(143\!\times\! 8^n-307\!\times\!4^n+193\!\times\! 2^n-32\right)\,(n+4)!\end{align}$$ This pattern seems to continue within increasingly complicated polynomials of 2^n on the right-hand side. Can you suggest an approach to prove these, and to find a more general formula for an arbitrary exponent k^{n+p}?

A curious infinite product of factorials

I found the following infinite product of factorials without proof: $$\small\prod_{n=1}^\infty\frac{{(2 n)!}^{20}\,{(8 n)!}^{32}\,{(32 n)!}^2}{{n!}^4\,{(4 n)!}^{37}\,{(16 n)!}^{13}}=\\\frac{\sin ^{14}\!\frac{\pi }{8}\cdot\sin \frac{\pi }{32} \cdot\sin \frac{3 \pi }{32} \cdot\sin \frac{5 \pi }{32} \cdot\sin \frac{7 \pi }{32}}{\sin ^6\!\frac{\pi }{16} \cdot\sin ^6\!\frac{3\pi }{16}}\cdot \frac{2^{1283/64}\,\pi^{14}\,\Gamma^{10} \!\left(\frac{1}{8}\right) \Gamma^2\! \left(\frac{5}{32}\right) \Gamma^2 \!\left(\frac{7}{32}\right)}{\Gamma^{18} \!\left(\frac{5}{8}\right) \Gamma^{10} \!\left(\frac{1}{16}\right) \Gamma^{10} \!\left(\frac{3}{16}\right) \Gamma^2 \!\left(\frac{17}{32}\right) \Gamma^2 \!\left(\frac{19}{32}\right)}.$$ We can verify that $$\small\frac{{(2 n)!}^{20}\,{(8 n)!}^{32}\,{(32 n)!}^2}{{n!}^4\,{(4 n)!}^{37}\,{(16 n)!}^{13}}=1+\mathcal O\left(n^{-3}\right),$$ so the product indeed converges. Can you suggest how to prove its closed form on the right? Is it possible to further simplify it? Is it possible to find a simpler convergent infinite product of this form (involving only integer powers of factorials of integer multiples of n)?

Integer solutions to $r\cdot a^2+t=s\cdot b^2$ forms sequences with $a_{n+1}\cdot b_n-a_n\cdot b_{n+1}$ is invariant

Conjecture: Given natural numbers r,s,t. Suppose there are an infinite number of solutions $a_n,b_n \in \mathbb N$ to $ra_n^2+t=sb_n^2$, where a_n, b_n correspond to increasing sequences of solutions, then $a_n\cdot b_{n+1} - a_{n+1}\cdot b_n$ is invariant equal for each n greater than some $N>0$. I've done a lot of tests without exceptions. The number N is typically ≤ 1. I would like to see ideas how to proceed. Some (r,s,t) values plus sets of (a,b) values: (1,2,1) {(1,1),(7,5),(41,29),(239,169),(1393,985),(8119,5741)} (2,1,1) {(0,1),(2,3),(12,17),(70,99),(408,577),(2378,3363)} (1,2,2) {(0,1),(4,3),(24,17),(140,99),(816,577),(4756,3363)} (3,2,2) {(0,1),(4,5),(40,49),(396,485),(3920,4801)} (2,3,1) {(1,1),(11,9),(109,89),(1079,881),(10681,8721)} There seems to be a matrix $ \begin{pmatrix} \alpha & ms \\ mr & \alpha \\ \end{pmatrix} $ that transform (a_{n},b_{n}) to (a_{n+1},b_{n+1}), but I haven't proved that and I'm insecure about α and m. It could be that $\alpha=\sqrt{m^2rs+1}$ and that the determinant is unital. The conjecture is false with counter-example (1,2,7) {(1,2),(5,4),(11,8),(31,22),(65,46),(181,128),(379,268)} What's left is Given $r,s,t\in\mathbb R_+$ and $S=\{(a,b)\in\mathbb R_+^2|rs^2+t=sb^2\}$, then it exist a sequence $(a_n,b_n)\in S$ such that: $$a_{n+1}b_n-a_nb_{n+1}=2t \tag 1$$ $$ \begin{pmatrix} a_{n+1} \\ b_{n+1} \\ \end{pmatrix} = \begin{pmatrix} \sqrt{4rs+1}& 2s \\ 2r & \sqrt{4rs+1} \\ \end{pmatrix} \begin{pmatrix} a_n\\ b_n \\ \end{pmatrix} \tag 2$$ which I consider as virtually proved by the accepted answer.

Can you spot the mistake here?

assume that : $$x^{3} + y^{3} = z^{3}$$ so : $$z^{3} - y^{3} = x^{3}$$ $$z^{3} ≡ y^{3}\bmod x$$ $$z ≡ y\bmod x $$ $$z-y = x $$ and now let's plug this result to the original equation: $$(z-y)^{3} + y^{3} = z^{3}$$ $$z^{3}-3z^{2}y+3zy^{2}-y^{3}+y^{3}=z^3$$ by simplfying, we get this: $$3zy^{2} = 3z^{2}y$$ dividing by $3zy$: $$y=z$$ so this equation has solutions if and only if $y = z$, and now let's plug our results to the original equation: $$x^{3}+y^{3} = y^{3}$$ $$x^{3} = 0$$ $$x = 0$$ Therefore :There is no solution when: $$x,y,z\in\mathbb{N}$$ and by mathematical induction we can prove it (instead of the power 3) for all $ n\in\mathbb{N}$

Does the following lower bound improve on $I(q^k) + I(n^2) > 3 - \frac{q-2}{q(q-1)}$, where $q^k n^2$ is an odd perfect number?

Let $N = q^k n^2$ be an odd perfect number with special prime q satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Define the abundancy index $$I(x)=\frac{\sigma(x)}{x}$$ where $\sigma(x)$ is the classical sum of divisors of x. Since q is prime, we have the bounds $$\frac{q+1}{q} \leq I(q^k) < \frac{q}{q-1},$$ which implies, since N is perfect, that $$\frac{2(q-1)}{q} < I(n^2) = \frac{2}{I(q^k)} \leq \frac{2q}{q+1}.$$ By considering the negative product $$\bigg(I(q^k) - \frac{2(q-1)}{q}\bigg)\bigg(I(n^2) - \frac{2(q-1)}{q}\bigg) < 0,$$ since we obviously have $$\frac{q}{q-1} < \frac{2(q-1)}{q},$$ then after some routine algebraic manipulations, we arrive at the lower bound $$I(q^k) + I(n^2) > 3 - \frac{q-2}{q(q-1)} = \frac{3q^2 - 4q + 2}{q(q - 1)}.$$ Now, a recent MO post improves on the lower bound for $I(n^2)$, as follows: $$I(n^2) > \bigg(\frac{2(q-1)}{q}\bigg)\bigg(\frac{q^{k+1} + 1}{q^{k+1}}\bigg)$$ Added February 3, 2021 - 8:10 PM (Manila time) Here is a quick way to show the improved lower bound for $I(n^2)$. We have $$I(n^2)=\frac{2}{I(q^k)}=\frac{2q^k (q - 1)}{q^{k+1} - 1}=\frac{2q^{k+1} (q - 1)}{q(q^{k+1} - 1)}=\bigg(\frac{2(q-1)}{q}\bigg)\bigg(\frac{q^{k+1}}{q^{k+1} - 1}\bigg)$$ $$=\bigg(\frac{2(q-1)}{q}\bigg)\bigg(\frac{(q^{k+1} - 1) + 1}{q^{k+1} - 1}\bigg)=\bigg(\frac{2(q-1)}{q}\bigg)\bigg(1 + \frac{1}{q^{k+1} - 1}\bigg)$$ $$>\bigg(\frac{2(q-1)}{q}\bigg)\bigg(1 + \frac{1}{q^{k+1}}\bigg)$$ since $q^{k+1} > q^{k+1} - 1$. But, of course, we obtain $$I(n^2)>\bigg(\frac{2(q-1)}{q}\bigg)\bigg(1 + \frac{1}{q^{k+1}}\bigg)=\bigg(\frac{2(q-1)}{q}\bigg)\bigg(\frac{q^{k+1} + 1}{q^{k+1}}\bigg).$$ QED. Repeating the same procedure as above, we have the negative product $$\Bigg(I(q^k) - \left(\frac{2(q-1)}{q}\bigg)\bigg(\frac{q^{k+1} + 1}{q^{k+1}}\right)\Bigg)\Bigg(I(n^2) - \left(\frac{2(q-1)}{q}\bigg)\bigg(\frac{q^{k+1} + 1}{q^{k+1}}\right)\Bigg) < 0.$$ This implies, after some algebraic manipulations, that $$I(q^k) + I(n^2) > \frac{q^{k+2}}{(q - 1)(q^{k+1} + 1)} + \frac{2(q-1)(q^{k+1} + 1)}{q^{k+2}}.$$ But WolframAlpha says that the partial fraction decomposition of the new lower bound is given by $$\frac{q^{k+2}}{(q - 1)(q^{k+1} + 1)} + \frac{2(q-1)(q^{k+1} + 1)}{q^{k+2}} = \frac{3q^2 - 4q + 2}{q(q - 1)} + \frac{2(q - 1)}{q^{k+2}} - \frac{q}{(q - 1)(q^{k+1} + 1)}.$$ So essentially, my question boils down to: QUESTION: Is it possible to produce an unconditional proof (that is, for all $k \geq 1$ and for all special primes $q \geq 5$) for the following inequality? $$\frac{2(q - 1)}{q^{k+2}} > \frac{q}{(q - 1)(q^{k+1} + 1)}$$ MY ATTEMPT I tried to ask WolframAlpha for a plot of the above inequality, it gave me the following GIF image: So it does appear that the inequality is unconditionally true, which would mean that the new lower bound for $I(q^k) + I(n^2)$ improves on the old. Is it possible to prove this analytically? And lastly: Based on this answer to a closely related question, since we appear to have obtained an improved lower bound for $I(q^k) + I(n^2)$, can we then say that there is indeed an integer a such that $k \leq a$?

Conjecture: primes non-decreasing from $(n,2n)$ to $(2n,4n)$.

More generally, I assert: $$\pi(na^k)-\pi(na^{k-1})\leq \pi(na^{k+1})-\pi(na^k)\quad\text{for }n,a,k \in \mathbb N.$$ The most useful case of this is probably to say that if there are m primes in $[n,2n]$, then there will be at least m primes in $[2n,4n]$. I thought it worth noting this can also be written as $$\pi(2n) \leq \frac{\pi(4n)+\pi(n)}{2}.$$ I doubt there are counterexamples, but if someone finds one, please share. Barring that, since this seems like an intermediate-strength statement, I'm curious how easy or difficult this might be to prove, and whether there are known similar results. Update Looks like a much tighter bound can also be specified below as $ \pi(3n)+\pi(n) \leq 2\pi(2n)$ for $n>1323$. Also, note this can be used in reverse. E.g. suppose we've worked out that the only primes in $[8,16]$ are 11 and 13. Then, even knowing nothing whatsoever about primes other than this rule (and that they start at 2), it follows that there could be at most 2 more primes in $[4,8]$, and another 2 in $[2,4]$, so we'd know that $\pi(13)\leq 6$.

Conjecture: if collatz(n) reaches 1, it must do so in at most 2^{n+1} steps

Let $f(n)$ give the number of Collatz iterations it takes to yield a number less than n, using the "shortcut" version of Collatz which applies $n\rightarrow (3n+1)/2$ for odds. Suppose it can be shown that $$f(n)=k \iff f(n+a2^k)=k\qquad \forall a\in\mathbb N.$$ So if a starting value of n decreases, it must happen in at most 2^n steps, and then we can say the same thing about that lower number, and so on, summing to a worst case upper bound of 2^{n+1} steps. My question: Is my reasoning correct, and if so, is this a known result? Per request, the reason I think I can show the above is based on the empirical results for $n<5\times 10^6$, which gives: The leftmost column is k, the number of steps required to reach a smaller number. The fourth column, obviously going as 2^k, is the period after which appearances of k repeat. There are multiple appearances of a given k within that period, e.g. for $k=5$ which shows up with alternating intervals of 12 and 20, but that's not required for my conjecture. This pattern strikes me as regular enough that I suspect a good reason for it would not be hard to work out. Of course, I could be wrong about that, but my question is whether the rest of my logic makes sense assuming a proper proof for this part exists. In fact, Wikipedia gives "... it can be shown that the parity sequences for two numbers m and n will agree in the first k terms if and only if m and n are equivalent modulo 2^k." Parity in this context refers to whether a step increases or decreases the number, so if the parity sequences are the same for two numbers, they will indeed both decrease below their original value on the same step number, which seems like it confirms my suspicion that the above is solid, but as Collag3n points out, is not quite proof. Couple of thoughts on $f(n)=k \iff f(n+a2^k)=k\qquad \forall a\in\mathbb N$: First, we still assert that $f(n)=k \implies f(n+a2^k)=k$. Then, let $f(n)=j$ and $f(n+2^k)=k$, where $j \neq k$. Note that $f(n)=j \implies f(n+a2^j)=j$. If $j<k$, then let $a=2^{k-j}$ and we have $f(n+a2^k)=f(n+(2^{k-j})2^j)=j=f(n+2^k)=k$ by the asserted implication, which is a contradiction. Experimentally, it looks like $f(n+2^m)>m$ until hitting $f(n+2^k)=k$. Note this would give $f(n+2^k)=k\implies f(n+2^{k-1})>f(n+2^k)$.

There are $2^{\omega(a)}$ pairs (b,c) such that $a=bc$ and $\gcd(b,c)=1$

It looks as there are $2^{\omega(a)}$ ordered pairs (b,c) such that $a=bc$ and $\gcd(b,c)=1$, where $\omega(a)$ is the number of different prime factors of a. Proof? It's also true that there are $n^{\omega(a)}$ n-tipples $(a_1,\dots ,a_n)$ such that $a=a_1\cdots a_n$.

How to prove $4\times{_2F_1}(-1/4,3/4;7/4;(2-\sqrt3)/4)-{_2F_1}(3/4,3/4;7/4;(2-\sqrt3)/4)\stackrel?=\frac{3\sqrt[4]{2+\sqrt3}}{\sqrt2}$

I have the following conjecture, which is supported by numerical calculations up to at least 10^5 decimal digits: $$4\times{_2F_1}\left(-\frac{1}{4},\frac{3}{4};\frac{7}{4};\frac{2-\sqrt{3}}{4}\right)-{_2F_1}\left(\frac{3}{4},\frac{3}{4};\frac{7}{4};\frac{2-\sqrt{3}}{4}\right)\,\stackrel?=\,\frac{3\sqrt[4]{2+\sqrt{3}}}{\sqrt{2}},$$ where $_2F_1$ denotes the hypergeometric function. Can you suggest any ideas how to prove it? The conjectural closed form was obtained using WolframAlpha query ToRadicals[RootApproximant[2.9484457662642558059990881423857006769923 3]]

Conjecture: For almost all n, the sum of $n \bmod k$ for $k<n$ is unique.

It looks to me like $$f(n):= \sum_{k=1}^{n}{(n\bmod k)}$$ is almost unique to n, with the only systematic exceptions being $(2^m-1, 2^m)$ pairs, which share a value for any $m \in \mathbb N$. In other words, the set $\{f(n): n\in\mathbb N\land n\neq 2^m \ \forall m\in\mathbb N\}$ shouldn't have many duplicate values. As discussed in the answers, a handful of counterexamples have been found, but they seem more sparse than one would expect, and nobody has yet suggested why that might be, or what's special about the counterexamples found, apart from a moderate preponderance of small factors in the mean of the pair. Although there's not much data to go on, it also looks like counterexamples may come in the form $(n,n+2i)$, or possibly even $(n,n+2^i)$, and I would be interested if anyone can find a case outside of those. The latter form would also include the $(2^m-1,2^m)$ exceptions, which seems elegant. Also, if someone could set me straight on this: My understanding is that the term 'almost all' in this context means approaching 0 density in the limit; so if one could show that the exceptions aren't necessarily finite, but they are less common than powers of two, would that be sufficient?

Conjecture of Differential Geometry Line Element identity?

Question Lets say I have a line element $ds^2 = \sum_{\mu , \nu = 0}^n g^{\mu \nu} d \tilde x_\mu d \tilde x_\nu $ and $1.$ It is of the form $ds^2 = \sum_{\mu=0}^n g^{\mu \mu} d \tilde x_\mu d \tilde x_\mu= \sum_{\mu=0}^n (d (\int \sqrt{g^{\mu \mu}} d\tilde x_\mu))^2 = \sum_{\mu=0}^n d x_\mu^2$. This form of the line element $\sum_{\mu=0}^n d x_\mu^2$ is achieved via coordinate transformation. If the square root is negative one can use $*$ $2.$ There exists a path whose path-length extends to infinity We define $s = \int_{\lambda_0}^{\lambda_1} \sqrt{\sum_{\mu=0}^n \frac{ds_\mu}{d \lambda} \frac{d s^\mu}{d\lambda}} d \lambda $ with $s(0)= 0 = \lambda_0$ 3. There is a unique one to one mapping between s and its coordinates x_i . For example,

$s(x_{0c},x_{1c},\dots) = c$ then $s = c \implies (x_0,x_1,x_2,\dots) = (x_{0c},x_{1c},x_{2c},\dots)$ Further the path taken has if s is expressed coordinates x_i $4.$ Then also impose $d x_i \neq 0 $. For example if $ds^2 = dx^2 + dy^2$ then $s_\mu = (x,0)$ is not a valid path because $ds_1= 0 $ (counting μ from 0). However, $s_\mu= (x,-y)$ is a valid path. Then we have the following identity: $$(\int_{s=0}^\infty e^{-\alpha s^2} ds)^2 = \sum_{i=0}^n (\int_{x_{i0}}^\infty e^{-\alpha s(x_i)^2} dx_i)^2 $$ $*$Note if $g^{j j}$ is negative then we use the same procedure with a negative sign. For example, $s_\mu = (t,x) = (\lambda, \lambda)$ $$ds^2 = - dt^2 + dx^2\implies (\int_{s=0}^\infty e^{-\alpha s^2} ds)^2 = -(\int_{t=0}^\infty e^{-\alpha s^2} dt)^2 + (\int_{x=0}^\infty e^{-\alpha s^2} dx)^2 =0 $$ Note: ds^2 is also 0 Are there any counterexamples? Can I use this to find the mapping between s and x_i? Does the formula still work if there isn't a unique mapping between s and its coordinates? Heuristic Rough Derivation and Example The following proof is difficult to follow but is meant to give only a rough sketch. We define $s = \int_{\lambda_1}^{\lambda_2} \sqrt{\sum_{\mu=0}^n \frac{ds_\mu}{d \lambda} \frac{d s^\mu}{d\lambda}} d \lambda $ For example, let's say I have the line element: $$ ds^2 = dx^2 + dy^2 + dz^2$$ Now we multiply a factor of $\lambda_s e^{-\alpha s(x,y,z)}$ both sides. Note: λ_s should not be thought as a function $$ \lambda_s e^{-\alpha s(x,y,z)}ds^2 = \lambda_s e^{-\alpha s(x,y,z)} dx^2 +\lambda_s e^{-\alpha s(x,y,z)} dy^2 + \lambda_s e^{-\alpha s(x,y,z)}dz^2 $$ Now we assume the path takes is continuous and has a mapping such that $s(x,y,z) = c $ implies there exists a unique set of coordinates (x_c,y_c,z_c) and $s(x_c ,y_c ,z_c) = c$. Further, the path chosen cannot be such that $dx = 0$ or $dy= 0$ or $dz= 0$. As an example let the path be $s(x,y,z)$. We then do a transformation based on this and cancel the common coefficient: $$(\int_{s=0}^\infty e^{-\alpha s^2} ds)^2 = (\int_{x_{0}}^\infty e^{-\alpha s(x,y(x),z(x))^2} dx)^2 + (\int_{y_{0}}^\infty e^{-\alpha s(x(y),y,z(y))^2} dy)^2 + (\int_{z_{0}}^\infty e^{-\alpha s(x(z),y(z),z))^2} dz)^2 $$ $s = \sqrt{3} \lambda$ with $x=y=z=\lambda$ with $x_0 = y_0 =z_0 = \lambda_0 = 0$ when $s=0$. Thus, $$ (\int_{s=0}^\infty e^{-\alpha s^2} ds)^2 = 3(\int_0^{\infty} e^{ - 3 \alpha x^2} dx)^2 = (\int_0^{\infty} e^{ - 3 \alpha x^2} d(\sqrt{ 3 }x))^2 $$ Hence the identity holds.

How can I prove this closed form for $\sum_{n=1}^\infty\frac{(4n)!}{\Gamma\left(\frac23+n\right)\,\Gamma\left(\frac43+n\right)\,n!^2\,(-256)^n}$

How can I prove the following conjectured identity? $$\mathcal{S}=\sum_{n=1}^\infty\frac{(4\,n)!}{\Gamma\left(\frac23+n\right)\,\Gamma\left(\frac43+n\right)\,n!^2\,(-256)^n}\stackrel?=\frac{\sqrt3}{2\,\pi}\left(2\sqrt{\frac8{\sqrt\alpha}-\alpha}-2\sqrt\alpha-3\right),$$ where $$\alpha=2\sqrt[3]{1+\sqrt2}-\frac2{\sqrt[3]{1+\sqrt2}}.$$ The conjecture is equivalent to saying that $\pi\,\mathcal{S}$ is the root of the polynomial $$256 x^8-6912 x^6-814752 x^4-13364784 x^2+531441,$$ belonging to the interval $-1<x<0$. The summand came as a solution to the recurrence relation $$\begin{cases}a(1)=-\frac{81\sqrt3}{512\,\pi}\\\\a(n+1)=-\frac{9\,(2n+1)(4n+1)(4n+3)}{32\,(n+1)(3n+2)(3n+4)}a(n)\end{cases}.$$ The conjectured closed form was found using computer based on results of numerical summation. The approximate numeric result is $\mathcal{S}=-0.06339748327393640606333225108136874...$ (click to see 1000 digits).

Yet another Collatz generalization and conjecture

Observe that Collatz (the $\frac{3n+1}{2}$ version) can be written as: $$n_{i+1}:= \begin{cases}n_i+\left\lceil\frac{n_i}{2}\right\rceil\quad\text{ if odd }n_i \\ n_i-\left\lceil\frac{n_i}{2}\right\rceil\quad\text{ if even }n_i \end{cases}$$ Looking at it this way gives the following pleasingly simple table for the difference between between consecutive terms, where $\Delta n := n_{i+1}-n_i$: $$ \begin{array}{|l|l|} \hline n_i&\Delta n\\ \hline 1&+1 \\ \hline 2&-1 \\ \hline 3&+2 \\ \hline 4&-2 \\ \hline 5&+3 \\ \hline \ldots&\ldots\\ \hline \end{array} $$ I apologize for not having worked out a nice short-form version of this, but consider a generalization of the above to give a construction like: $$ \begin{array}{|l|l|} \hline n_i&\Delta n\\ \hline 1&+1 \\ \hline 2&+2 \\ \hline 3&-1 \\ \hline 4&-2 \\ \hline 5&+3 \\ \hline 6&+4 \\ \hline 7&-3 \\ \hline 8&-4 \\ \hline 9&+5 \\ \hline \ldots&\ldots\\ \hline \end{array} $$ In fact, let k be the number determining that cyclic count, so that $k=1$ for the standard Collatz in the first table, and $k=2$ in the second table, and $k=3$ would give $\{1,2,3,-1,-2,-3,4,5,6,-4\ldots\}$. And by that definition, let $f(n,k)$ return the corresponding Δn using k as described. Then the next term for regular Collatz could be found as $C(n):=n+f(n,1)$. More generally, let's define $$C_k(n):=n+f(n,k),$$ so e.g. by examining that second table, we see that $C_2(8)=8-4=4$ and $C_2(9)=14$. This construction seems like it might have some interesting properties. In particular, I conjecture that $\forall k,n\in\mathbb N : C_k(n)$ will eventually reach k, assuming Collatz itself holds. Furthermore, if you take any such sequence and number it starting with $S_0=n$, it seems we have $$\gcd(S_i,k) \leq \gcd(S_{i+1},k).$$ This means that once you have $k|S_j$ for some j, all future terms can be divided through by k to give a standard Collatz sequence, but this is definitely not the case before reaching S_j. I'm interested to see if anyone can find a counterexample or simple reason why this should or should not hold. Any reasonably constructive feedback would be acceptable as an answer, and of course if this has been investigated before, by all means let me know. Sample Mathematica code if anyone wants it: Clear[f, c]; SetAttributes[{f, c}, Listable]; f[n_, k_] := With[{m = Mod[n, 2 k, 1]}, If[m <= k, 1, -1] (Floor[(n - 1)/(2 k)] (k) + Mod[n, k, 1])] c[n_, k_] := NestWhileList[# + f[#, k] &, n, # != k &, 1, 1000] c[27, Range[6]] // Column will give you sequences for $C_k(27)$ for $k \leq 6$.

Differential Geometry Inequality Conjecture?

Question and Conjecture In a Lorentzian metric (Only one time dimension) of signature: $(+,-,-,-,\dots)$ Lets say I have a line element $ds^2 = \sum_{\mu , \nu = 0}^n g^{\mu \nu} d \tilde x_\mu d \tilde x_\nu $ and $1.$ It is of the form $ds^2 = \sum_{\mu=0}^n g^{\mu \mu} d \tilde x_\mu d \tilde x_\mu$ $2.$ There exists a continuous path

parametrized by λ whose path-length extends to infinity We define $s = \int_{\lambda_0}^{\lambda_1} \sqrt{\sum_{\mu=0}^n \frac{d \tilde x_\mu}{d \lambda} \frac{d \tilde x^\mu}{d\lambda}} d \lambda $ with $s(0)= 0 = \lambda_0$ $3.$ It must be of the Lorentzian only g_{00} must be positive and the path must be timelike. Then: We define: $$ g^{00} ds'^2 = ds^2 $$ and define coordinates: $d x_i = \sqrt{|g^{ii}|} d \tilde x_i$. Then: $$(\int_{s(\lambda_0)=0}^\infty e^{-\alpha s'^2} ds')^2 \geq (\int_{\lambda_0}^\infty e^{-\alpha s(x (\lambda),y(\lambda),z(\lambda))^2} \frac{dx_0}{d \lambda} d \lambda)^2 - \sum_{\mu=1}^n (\int_{\lambda_0}^\infty e^{-\alpha s(x(y),y,z(y))^2} \frac{d x_\mu}{d \lambda} d \lambda)^2 $$ Are there any counter examples? Heuristic Rough Derivation and Example The following proof is difficult to follow but is meant to give only a rough sketch. We define s as done already previously now let's say I have the line element: $$ ds^2 = f(r,t)^2 dt^2 - r^2 d\theta^2 - dr^2 $$ We compare this to: $$ f(r,t) ds' = ds $$ Hence, $$ ds'^2 = dt^2 - \frac{dr^2}{f(r,t)^2} - \frac{r^2}{f(r,t)^2} d \theta^2 $$ Now we multiply a factor of $\beta_s e^{-\alpha s'(x,y,z)}$ both sides. Note: β_s should not be thought as a function $$ \beta_s e^{\alpha s'} ds'^2 = e^{\alpha s'} \beta_s dt^2 - \beta_s e^{\alpha s'} \frac{dr^2}{f(r,t)^2} - \beta_s e^{\alpha s'} \frac{r^2}{f(r,t)^2} d \theta^2 $$ Let: $$ \beta_s e^{\alpha s'} ds'^2 = e^{\alpha s'} \beta_s dt^2 - \beta_s e^{\alpha s'} \frac{dr^2}{f(r,t)^2} - \beta_s e^{\alpha s'} \frac{r^2}{f(r,t)^2} d \theta^2 $$ We can also say: $$\beta_s e^{\alpha s'} ds'^2 \geq e^{\alpha s'} \beta_s dt^2- \beta_s e^{\alpha s'} (d \int \frac{ dr}{f(r,t)})^2 - \beta_s e^{\alpha s'} (d \int \frac{r}{f(r,t)} d \theta)^2 $$ We define $y = \int \frac{ dr}{f(r,t)} $ and $z = \int \frac{r}{f(r,t)} d \theta$ Now we assume the path takes is continuous. We then do a transformation based on this and cancel the common coefficient: $$(\int_{s(\lambda_0)=0}^\infty e^{-\alpha s'^2} ds')^2 \geq (\int_{\lambda_0}^\infty e^{-\alpha s(x (\lambda),y(\lambda),z(\lambda))^2} \frac{dt}{d \lambda} d \lambda)^2 $$ $$- (\int_{y(\lambda_0)}^\infty e^{-\alpha s(x(y),y,z(y))^2} \frac{dy}{d \lambda} d \lambda)^2 - (\int_{\lambda_0}^\infty e^{-\alpha s(x(z),y(z),z))^2} \frac{dz}{d \lambda} d \lambda)^2 $$

Is this Pythagorean triple formula original?

I am hesitant because I have asked this question before in a different form here. In 2009, I knew nothing about Pythagorean triples, not even Euclid's formula. In my ignorance, I did a brute force search, and the patterns I saw led to a formula for generating them. Years later, when I learned about Euclid's formula, it was confusing and I questioned it here. I'm an amateur but what I have found has kept me plodding along for over a decade. I developed a formula that should have been discovered in the 2300 years since Euclid. It generates the subset of triples where $GCD(A,B,C)$ is an odd square and this includes all primitives--without the trivials, the doubles and the even-square multiples of Euclid's formula. The formula is like Euclid's $ \quad A=m^2-k^2,\quad B=2mk,\quad C=m^2+k^2\quad$ but, as I discovered later, with $\space m\space$ replaced by $\space (2m-1+k)\space$ and this is why I show them both with a $\space k.\space$ This formula generates non-trivial triples for every pair of natural numbers (n,k) and very few non-primitives. Here is \begin{align*} A=(2n-1)^2+ &\quad 2(2n-1)k \\ B= \qquad &\quad 2(2n-1)k+ \quad 2k^2\\ C=(2n-1)^2+ &\quad 2(2n-1)k+ \quad 2k^2\\ \end{align*} It produces "sets" of triples where non-primitives like $\space(27,36,45)\space$ are in predictable/avoidable locations. \begin{array}{c|c|c|c|c|c|} n & k=1 & k=2 & k=3 & k=4 & k=5 \\ \hline Set_1 & 3,4,5 & 5,12,13& 7,24,25& 9,40,41& 11,60,61 \\ \hline Set_2 & 15,8,17 & 21,20,29 &27,36,45 &33,56,65 & 39,80,89 \\ \hline Set_3 & 35,12,37 & 45,28,53 &55,48,73 &65,72,97 & 75,100,125 \\ \hline Set_{4} &63,16,65 &77,36,85 &91,60,109 &105,88,137 &119,120,169 \\ \hline Set_{5} &99,20,101 &117,44,125 &135,72,153 &153,104,185 &171,140,221 \\ \hline Set_{6} &43,24,145 &165,52,173 &187,84,205 &209,120,241 &231,160,281 \\ \hline \end{array} $\text{If }\space(2n-1)=1\space $ or $\space k=1,\space $ triples are primitive: $\quad C-B=1\space \lor\space C-A=2.$ $\text{If }\space(2n-1)\space$ is prime, the following formula will generate only primitives. It repeatedly generates $\quad\big((2n-1)-1\big)\quad $ primitives and then skips a predicted non-primitive. \begin{align*} &A=(2n-1)^2+&2(2n-1)\bigg(k+\bigg\lfloor\frac{(k-1)}{(2n-2)}\bigg\rfloor\bigg)&\qquad\\ &B=&2(2n-1)\bigg(k+\bigg\lfloor\frac{(k-1)}{(2n-2)}\bigg\rfloor\bigg)&\qquad+2\bigg(k+\bigg\lfloor\frac{(k-1)}{(2n-2)}\bigg\rfloor\bigg)^2\\ &C=(2n-1)^2+&2(2n-1)\bigg(k+\bigg\lfloor\frac{(k-1)}{(2n-2)}\bigg\rfloor\bigg)&\qquad+2\bigg(k+\bigg\lfloor\frac{(k-1)}{(2n-2)}\bigg\rfloor\bigg)^2 \end{align*} 3) Else, there is a non-primitive whenever $\space k\space$ is a multiple of any factor of $\space(2n-1).$ I have not been able to find reference anything like this formula or the sets it generates in the many books I've bought on the subject or on web sites or in forums like this. Is this formula original with me or is there someone, somewhere or something I should cite in my references?

V3-019146 | MSE-404222

How to prove $\int_0^\infty J_\nu(x)^3dx\stackrel?=\frac{\Gamma(1/6)\ \Gamma(1/6+\nu/2)}{2^{5/3}\ 3^{1/2}\ \pi^{3/2}\ \Gamma(5/6+\nu/2)}$?

I am interested in finding a general formula for the following integral: $$\int_0^\infty J_\nu(x)^3dx,\tag1$$ where $J_\nu(x)$ is the Bessel function of the first kind: $$J_\nu(x)=\sum _{n=0}^\infty\frac{(-1)^n}{\Gamma(n+1)\Gamma(n+\nu+1)}\left(\frac x2\right)^{2n+\nu}.\tag2$$ Mathematica gives the following result: $$\int_0^\infty J_\nu(x)^3dx=\frac1{\pi\,\nu}{}_3F_2\left(\frac12,\frac12-\nu,\frac12+\nu;1-\frac\nu2,1+\frac\nu2;\frac14\right)+\frac{\Gamma\left(-\frac\nu2\right)\Gamma\left(\frac{1+3\nu}2\right)\cos\frac{\pi\,\nu}2}{2^{\nu+1}\ \pi^{3/2}\ \Gamma(\nu+1)}{}_3F_2\left(\frac{1-\nu}2,\frac{1+\nu}2,\frac{1+3\nu}2;1+\frac\nu2,1+\nu;\frac14\right),\tag3$$ which can be significantly simplified for odd and half-integer values of ν. The results at those points allow to conjecture another, simpler general formula: $$\int_0^\infty J_\nu(x)^3dx\stackrel?=\frac{\Gamma\left(\frac16\right)\ \Gamma\left(\frac16+\frac\nu2\right)}{2^{5/3}\ 3^{1/2}\ \pi^{3/2}\ \Gamma\left(\frac56+\frac\nu2\right)},\tag4$$ which agrees with (3) to a very high precision for many different values of ν. It also has an advantage that it is defined for all $\nu>-\frac13$ whereas (3) is undefined at every even ν and requires calculating a limit at those points. Is it possible to prove the formula (4)? Mathematica is able to

evaluate (1) for even values of ν in terms of the Meijer G-function. Plugging those expressions into (4) we get another form of the conjecture: $$G_{3,3}^{2,1}\left(\frac14\left|\begin{array}{c}2a,1,2-2a\\\frac12,1-a,a\\\end{array}\right.\right)\stackrel?=\frac{\Gamma\left(\frac16\right)\ \Gamma\left(\frac23-a\right)}{2^{5/3}\ 3^{1/2}\ \pi\ \Gamma\left(\frac43-a\right)}.\tag5$$ Incidentally, the case $a=\frac12$ would positively resolve my another question.

Is $K\left(\frac{\sqrt{2-\sqrt3}}2\right)$ equal to $\frac{\Gamma\left(\frac16\right)\Gamma\left(\frac13\right)}{4\ \sqrt[4]3\ \sqrt\pi}$?

Working on this conjecture, I found its corollary, which is also supported by numeric calculations up to at least 10^5 decimal digits: $$K\left(\frac{\sqrt{2-\sqrt3}}2\right)\stackrel?=\frac{\Gamma\left(\frac16\right)\Gamma\left(\frac13\right)}{4\ \sqrt[4]3\ \sqrt\pi},$$ where $K(x)$ is the complete elliptic integral of the 1st kind. I did not find this specific value at MathWorld, Wolfram Functions Site, Wikipedia or DLMF. Is it a known value?

Product of Consecutive integers problem

Product of Consecutive integers problem I've begun pondering the following problem, and have found myself unable to advance on it; it goes like this: Prove that the product of three consecutive integers is never the product of two consecutive integers (with a finite number of exceptions). Now, I basically have very little idea of what to work with. Obviously, I have two exceptions: {1, 2, 3} ($1 \times 2 \times 3 = 2 \times 3$) and {5, 6, 7} ($5 \times 6 \times 7 = 14 \times 15$). I formed the following equations: $x(x-1)(x+1) = y(y+1)$ ==> $x^3 - x = y^2 + y$ But I have no idea where to go from here. Graphing this on desmos yields the following elliptical curve, which I don't think helps me: How do I prove/ this conjecture?

A Question on Integers and Fractions

Given that a,b,c,d,e,f are all distinct positive integers, prove that there are no solutions for the following knowing their fractions are non-integers and completely simplified: $$\left(\frac{a}{c}\right)^2 + \left(\frac{b}{d}\right)^2 = e^2 \tag{1}$$ I coulden't find a proof for this one but I managed to prove this for the case of $$\left(\frac{a}{c}\right)^2 + \left(\frac{b}{d}\right) ^2 = \left(\frac{e}{f}\right)^2 \tag{2}$$ by simplifying: $$\frac{(ac)^2 + (bd)^2}{(cd)^2} = (\frac{e}{f})^2 $$ Since $(ac)^2 + (bd)^2$ must satisfy a Pythagorean triple, we know that each side length(exculding the hypotenuse) must be the product of two distinct integers, which can be proven through Euclid's formula : $$ac = (2m)(n)$$ $$bd = (m -n)(m + n)$$ Q.E.D. I also noted that (1) can be written as: $$(ac)^2 + (bd)^2 = (ecd)^2$$ This lead me to conjecture that there are no Pythagorean triples where the hypotenuse has 2 distinct integer factors where one of each is shared with its side lengths. Furthermore, I also conjecture the hypotenuse's remainder must be a prime such that those conditions can never be satisfied. Can anyone prove or disprove this?

Proof of conjecture about orthogonalized Specht polynomials.

Let $\lambda=(\lambda_1,\lambda_2,\ldots,\lambda_r)$ be a r-part partition of integer N ($\lambda\vdash N$), i.e., $$\sum_{i=1}^r{\lambda_i}=N,$$ such that $\lambda_i\leq\lambda_j$ for $r\geq j>i\geq1$. Thus, λ defines a Young diagram. In addition, let $\mathbf{y}^{(k)}_{\lambda}$ be the kth standard Young tableau, SYT, of shape λ, i.e., the array of numbers $1\leq y_{i,j}\leq N$ that fulfills $y_{i,j}>y_{i-1,j}$ $y_{i,j}>y_{i,j-1}$ for indices $1\leq i \leq r$ and $1 \leq j \leq\lambda_i$. The number of possible SYT of shape λ is $\dim S^\lambda$, the dimension of the Specht module. Moreover, let us define the permutation operator $\hat{\pi}=(\hat{\pi}_1,\hat{\pi}_2,\ldots,\hat{\pi}_r)$, such that $$\mathbf{w}=\hat{\pi}\mathbf{y},$$ where $\textrm{row}_i[\mathbf{w}]=\hat{\pi}_i\textrm{row}_i[\mathbf{y}]$, with $\textrm{row}_i[\mathbf{w}]$ the ith row of array $\mathbf{w}$, and $\hat{\pi}_i\in S_{\lambda_i}$. Finally, let $$\textrm{Spe}\left(\mathbf{w}\right)=\prod_{i=1}^{\lambda_1}V\left(\textrm{col}_i[\mathbf{w}]\right)$$ be the Specht polynomial for the (not-necessarily standard) Young tableau $\mathbf w$, where $\textrm{col}_i[\mathbf{w}]$ is the ith column of array $\mathbf{w}$, and $$V\left(a_1,a_2,\ldots,a_n\right)=\prod_{1\leq j<k\leq n}(x_{a_j}-x_{a_k})$$ is the Vandermonde determinant of set $\{a_1,a_2,\ldots,a_n\}$. After playing around with Gram-Schmidt orthogonalization, I have formulated the following conjecture: The set of polynomials $$\left\{p_\lambda^{(k)}\left(x\right):1\leq k\leq \dim S^\lambda\right\},$$ where $x=\{x_i:1\leq i\leq r\}$, $$p_\lambda^{(k)}\left(x\right)=\sum_{c}\textrm{Spe}\left(\mathbf{w}_\lambda^{(c,k)}\right),$$ and $\mathbf{w}_\lambda^{(c,k)}=\hat{\pi}^{(c)}\mathbf{y}_\lambda^{(k)}$, with the index c running over all possible permutation operators that produce Young tableaux with the constraint $$w_{i,j}>w_{i,j-1},$$ forms an orthogonal basis in the domain $-1/2\leq x_{1\leq i\leq r} \leq 1/2$, i.e., $$\int_{-1/2}^{1/2} p_\lambda^{(k)}(x)p_\lambda^{(k')}(x)\textrm{d}^{r}x\propto\delta_{k,k'}.$$ My question is, how can I go about a general proof that does not involve checking case by case and performing all inner products one by one?

Progress on a conjecture of Burnside...

Given a group $G $, the set of automorphisms of $G $ also forms a group, $\rm {Aut}(G) $,with composition as the operation (recall that an automorphism of a group is a bijective endomorphism) . An inner automorphism is one determined by conjugation by some element $g\in G $. That's we have the automorphism $i_g $ given by $i_g (h)=ghg^{-1}\,\forall h $. I learned from a comment by @LeeMosher on this site that Burnside once conjectured that any class-preserving automorphism is inner. Does anyone know about any progress on this? Of course the converse is trivial. (Btw, the reference here is to conjugacy classes. Of course the class equation gives the sizes of these classes. For example, in the case of an abelian group, the class equation consists in all ones.) For reference, this would have been early in the 20-th century.

Is there any algorithm generating "all" chrodal graphs of order n?

I defined a procedure Γ to generate graphs following some rules. The obtained graphs form a class of graphs $\mathcal{G}$. I found out that these graphs are chrodal. In the other hand, I noticed that every chordal graph of order 3 and 4 can be constrcuted by the procedure Γ. I implemented an algorithm that generates all $\mathcal{G}$-graphs with n vertices. But I need some algorithm that constructs all the chordal graphs with n vertices in order to make the following conjecture more plausible. Let G be a graph. Then G belongs to $\mathcal{G}$ if and only if G is chordal. I want to show that every graph obtained by such an algorithm can also be obtained by the procedure Γ. So, my question is: Does any algorithm generating all chordal graphs exist?

Asymptotic series for the inverse Riemann ζ-function

Consider the positive branch of the Riemann ζ-function: $\zeta:(1,\infty)\to(1,\infty)$ and its inverse $\zeta^{\small(-1)}:(1,\infty)\to(1,\infty)$ satisfying $\zeta\left(\zeta^{\small(-1)}(x)\right) = x$ for $x>1$. Here are a few initial terms of an asymptotic expansion of $\zeta^{\small(-1)}$ in powers of x (except for the initial term that is logarithmic): $$\begin{align}\zeta^{\scriptscriptstyle(-1)}(1+x)=-\log_2x+{\small\frac1{\ln2}}\Big(&x^{\log_2\left(\frac32\right)}+x+{\small\log_2\left(\tfrac{\sqrt2}3\right)}\cdot x^{2\log _2\left(\frac32\right)}\\+\,&x^{\log _2\left(\frac52\right)}-{\small\log_2 3}\cdot x^{\log_23}\Big)+\mathcal O\Big(x^{3\log_2\left(\frac32\right)}\Big)\color{gray}{,\,x\to0^+,}\end{align} $$ or, equivalently, $$\begin{align}\zeta^{\scriptscriptstyle(-1)}\left(1+2^{-z}\right)=z+{\small\frac1{\ln2}}\Big(&\left(\tfrac32\right)^{-z}+{\small2^{-z}}+{\small\log_2\left(\tfrac{\sqrt2}3\right)}\cdot \left(\tfrac32\right)^{-2z}\\+\,&\left(\tfrac52\right)^{-z}-{\small\log_2 3}\cdot {\small3^{-z}}\Big)+\mathcal O\Big(\left(\tfrac32\right)^{-3z}\Big)\color{gray}{,\,z\to\infty.}\end{align} $$ Can we compute more terms of this series or find a general formula for its terms? Does this series converge?

Addition to previously asked question on Generalized Carmichael Numbers

I had previously asked a question on mathstack exchange (Conjecture on The Generalized Carmichael Numbers) concerning with a conjecture I had discovered. I worked on the problem for a long time and discovered one more conjecture. With the same terms and notations explained in the previous question (Conjecture on The Generalized Carmichael Numbers) The new conjecture goes as follows: Let $k \geqslant 1$, we have $$\lim_{n \to \infty}\dfrac{\mid C_{-k} \text{ }\cap \text{ } (0, X]\mid}{\mid C_{k} \text{ }\cap \text{ } (0, X]\mid - \left(\pi\left(\dfrac{X}{k}\right)\dfrac{\gcd(\lambda(k), k)}{\lambda(k)}\right)} = 1$$ where $\pi(X)$ is the prime-counting function. Also Note that For $k \geqslant 1$, we have: $C_k = $ Generalized Carmichael Numbers + $k\left(\text{primes} \equiv 1 \mod\left(\dfrac{\gcd(\lambda(k), k)}{\lambda(k)}\right)\right)$ For $k \leqslant 0$, we have C_k = Generalized Carmichael Numbers. I have worked on this conjecture for a long time but I'm not sure why the phenomenon is happening. I have used lot of brute force (computer program) for checking and verifying the conjecture for some large values and seems like it works. Any help or advice on how to proceed further would be appreciated. I really appreciate your time and efforts. Thanks.

Is there an odd x such that $2x^2 \equiv 0 \pmod {\sigma(x)}$ and $\sigma(x^2) \equiv 0 \pmod {\sigma(x) - 1}$?

CONTEXT This question is a result of considerations stemming from this closely related MO question. INITIAL QUESTION My question is as is in the title: Is there an odd x such that $$2x^2 \equiv 0 \pmod {\sigma(x)}$$ and $$\sigma(x^2) \equiv 0 \pmod {\sigma(x) - 1}?$$ Here, $\sigma(x)=\sigma_1(x)$ is the classical sum of divisors of x. MY ATTEMPT I tried searching for solutions to the congruences using GP in Sage Cell Server, I obtain: For both congruences for(x=2, 10000000, if((Mod(2*x^2,sigma(x)) == 0) && (Mod(sigma(x^2),sigma(x)-1) == 0),print(x,factor(x)))) No output returned. for(x=2, 1000000, if((Mod(2*x^2,sigma(x)) == 0) && (Mod(sigma(x^2),sigma(x)-1) == 0),print(x,factor(x)))) No output returned. For the congruence $2x^2 \equiv 0 \pmod {\sigma(x)}$ for(x=2, 10000000, if((Mod(2*x^2,sigma(x)) == 0),print(x,factor(x)))) Several lines returned. Will confirm if everything so far are even: 6[2, 1; 3, 1] 28[2, 2; 7, 1] 30[2, 1; 3, 1; 5, 1] 84[2, 2; 3, 1; 7, 1] 120[2, 3; 3, 1; 5, 1] 364[2, 2; 7, 1; 13, 1] 496[2, 4; 31, 1] 672[2, 5; 3, 1; 7, 1] 840[2, 3; 3, 1; 5, 1; 7, 1] 1080[2, 3; 3, 3; 5, 1] 1488[2, 4; 3, 1; 31, 1] 1782[2, 1; 3, 4; 11, 1] 2280[2, 3; 3, 1; 5, 1; 19, 1] 3276[2, 2; 3, 2; 7, 1; 13, 1] 3472[2, 4; 7, 1; 31, 1]

Term for example that is counterexample for "Conjecture A AND Conjecture B"

I am looking at something where there are two conjectures, Conjecture A and Conjecture B. I have Example X. It isn't a counterexample for Conjecture A or for Conjecture B but it is a counterexample for "Conjecture A and Conjecture B". That is, if Conjecture A is true, then Example X is a counterexample to Conjecture B; and if Conjecture B is true, then Example X is a counterexample to Conjecture A. It is (alas) not true that Example X implies that Conjecture A exclusive-or Conjecture B is true. It probably isn't natural to bundle Conjectures A and B into Conjecture C, and call Example X a counterexample to Conjecture C. Is there a name for such a counterexample? I have a short note and it would be nice to have a nice title and an answer to the question might help.

Could the discovery of a counterexample to the Unit Conjecture change mathematicians' understanding of spinors in general?

Recently it has been reported that Giles Gardham has found a counterexample to the Unit Conjecture for group rings, as given in https://arxiv.org/abs/2102.11818 (and also in a popular article https://www.quantamagazine.org/mathematician-disproves-group-algebra-unit-conjecture-20210412/) Being from a chemistry background with an interest in spinors (not myself a mathematician), I have been advised that a spinor can be defined, from a mathematician's viewpoint, as "a unit length element of a division algebra". (I do know what division algebras are, but am not a competent algebraist.) Assuming division algebras can contain group rings, then could the discovery of a counterexample to the Unit Conjecture lead to significant changes in the way mathematicians view spinors in general?

Continued fraction for Apéry's constant conjectured by The Ramanujan Machine

Recently the following identity was conjectured by The Ramanujan Machine: $$ \frac{8}{7\zeta(3)}=1-\frac{u_1}{v_1-\frac{u_2}{v_2-\frac{u_3}{v_3-\ddots}}}, $$ where $u_n=n^6$ and $v_n=(2n+1)(3n^2+3n+1)$. It has not yet been proven (authors are not aware of a proof), however this is somewhat similar to known cfrac in this answer, the main difference there being $v_n=(2n+1)(17n^2+17n+5)$. I couldn't prove it (to be expected), but I've found a following observation. The polynomial $(2n+1)(17n^2+17n+5)$ above is in various related articles used in certain recurrence which is satisfied by an integer sequence (see for example section 3 in Apéry's theorem. Thirty years after): $$ (n+1)^3r_{n+1}-(2n+1)(17n^2+17n+5)r_n+n^3r_n=0. $$ But in the paper of A Proof that Euler Missed (footnote page 202) we can find the conjectured polynomial $(2n+1)(3n^2+3n+1)$ to be in similar recurrence as well (after shift on n): $$ (n+1)^3r_{n+1}-2(2n+1)(3n^2+3n+1)r_n-(4n+1)4n(4n-1)r_{n-1}=0. $$ This recurrence is mentioned to be satisfied by integer sequence $r_n=\sum_{k=0}^n\binom{n}{k}^4$ (apparently with $r_0=1$ and $r_1=2$). Can this observation be any helpful in proving the conjecture, or is this just coincidence? Maybe do you see another way to prove it? (the problem has not been open for that long, so who knows...) EDIT: One more instance of the same polynomial, we have $$ \sum_{k=0}^{\infty} \frac{1}{(3k+1)^3}-\sum_{k=0}^{\infty} \frac{1}{(3k+2)^3}=\frac{4\pi^3\sqrt{3}}{243}=\frac{1}{P(1)+\frac{3\cdot 1^6}{P(2)+\frac{3\cdot 2^6}{P(3)+\dots}}} $$ where $P(n)=6n^3-9n^2+5n-1=(2n-1)(3n^2-3n+1)$ (the first equality is well known, the second equality is found in https://lfant.math.u-bordeaux.fr/seminar/slides/2019-11-05T10:00--Henri_Cohen.pdf). Also notice $$ \frac{1}{9}((3n+1)^3+(3n+2)^3)=(2n+1)(3n^2+3n+1). $$

"Goldbach's other conjecture" and Project Euler - writing 1 as a sum of a prime and twice a square

From Problem 46 of Project Euler : It was proposed by Christian Goldbach that every odd composite number can be written as the sum of a prime and twice a square. $$9 = 7 + 2 \cdot 1^2$$ $$15 = 7 + 2 \cdot 2^2$$ $$21 = 3 + 2 \cdot 3^2$$ $$25 = 7 + 2 \cdot 3^2$$ $$27 = 19 + 2 \cdot 2^2$$ $$33 = 31 + 2 \cdot 1^2$$ It turns out that the conjecture was false. What is the smallest odd composite that cannot be written as the sum of a prime and twice a square? As soon as I read this problem, I've immediately fought that the smallest odd number 1 was not on the list of examples. Then I've thought that 1 can be the answer. The only way that I could write 1 close to the problem $1=1+2 \cdot 0^2$, Which is of course false. I've also tried to give 1 as answer, but the site didn't accepted. So how can we write 1 as a sum of a prime and twice a square?

A conjecture about binary palindromes and arithmetic derivatives

Corrected question. From the sequence of binary palindromes A006995 (eg. 1001001001001) the sequence of possible gaps between consecutive palindromes contain the elements: S={2,4,6,8,12,16,24,32,48,64,96,128,192,256,384,512,768,1024,1536,2048,3072,4096,6144,8192,12288,16384,24576,49152,...} Compare with A131117 that correspond to the set of positions of the records in the sequence of arithmetic derivatives. T={2,4,6,8,12,16,24,32,48,64,96,128,192,256,384,512,640,768,960,1024,1280,1536,1920,2048,2560,3072,3584,3840,4096,5120,6144,7168,7680,8192,10240,12288,14336,15360,16384,20480,24576,28672,30720,32768,40960,...} This prompts for the conjecture that $S\subseteq T$ A hint of a proof may be to much to ask for, but are there computational results that support or contradicts the conjecture? S comes from gaps of consecutive palindromes in the $100,000,000$ first palindromes >0.

Follow-up to question 3121498, asked in February 2019

Let $n = p^k m^2$ be an odd perfect number given in Eulerian form (i.e. p is the special/Euler prime satisfying $p \equiv k \equiv 1 \pmod 4$ and $\gcd(p,m)=1$). Denote the classical sum of divisors of the positive integer x by $\sigma(x)=\sigma_1(x)$. This question (and the answer contained therein) presented a proof of the following proposition, the first conditional on the hypothesis that $\sigma(m^2)/p^k$ is a square, and the second one was unconditional: If $n = p^k m^2$ is an odd perfect number with special prime p, then $m^2 - p^k$ is not a square. In both proofs, the equation $p^k + 1 = 2m$ was obtained, and was shown to lead to a contradiction. Here are my questions: (1) Does the contradiction imply that the inequation $p^k + 1 \neq 2m$ holds for all odd perfect numbers $n = p^k m^2$, in general? (2) If the answer to Question (1) is YES, which of the following inequalities hold in general for an odd perfect number? (a) $p^k + 1 < 2m$; or (b) $p^k + 1 > 2m$? MY ATTEMPT I figured this much from this closely related MathOverflow question, where we tried to disprove the Dris Conjecture (that $p^k < m$) and therefore the Descartes-Frenicle-Sorli Conjecture (that $k=1$) in one fell swoop. However, we were unsuccessful, as Pascal Ochem pointed out that our method required that $p^k \geq 2m - 1$.

Checking a conjecture on prime numbers

Thinking on Oppermann and Goldbach conjectures, it came to me the following conjecture that mixes some aspects of both of them: Let $n\notin\mathbb{P}$; then, there exist some prime numbers p and q such that $n^2-n<p<n^2<q<n^2+n$ such that $p+q=2n^2$ I have been checking first cases "by hand", and I would like to know if there exists an "easy" way to check if the conjecture is true or has some inmediate counterexample. I tried programming something in Excel but it was too messy. Thanks in advance!

Subtraction puzzle conjecture

I recently learned about a puzzle called a "Diffy". You take four numbers positioned at the vertices of a square. On the midpoint of each side, you write the difference of the two numbers on the vertices of that side. Once you have done this for all four sides, you connect the four new numbers with a square and repeat. My conjecture is that it always comes to four zeroes, if we repeat to infinity. I have not yet been able to prove this, though I tried with variables w, x, y, z as the corners of the square. Unfortunately, I ended up with math mush. Can someone help me prove or disprove this?

Prove conjecture about circle pairing centers

I'm desperately trying to prove a statement which I need for some other results in my bachelor final project (I already spent several hours on this and it's driving me crazy). I would be very happy if you could help me, and if you can you will get credited in my bachelor final project report. Here are some definitions, theorems and terminology. Definition: a circle pairing f is a Möbius transformation which maps the exterior of a circle C_F to the interior of a circle C_f, and it maps the interior of C_F to the exterior of C_f (and from this follows that it maps C_F onto C_f). Terminology: for a circle pairing f as above, the circle C_f has center C_1, and the circle C_F has center C_2. Theorem: for any given triple of points there is a unique Möbius transformation which maps these three points to any other given triple of points. Theorem: Möbius transformations map circles and lines to circles or lines. The statement I want to prove: For every circle pairing f the circles C_F and C_f which are paired as above can be chosen such that f maps the point at infinity to C_1, and maps C_2 to the point at infinity. Assume that the point at infinity lies in the exterior of both circles which are paired. My question is if you can prove this, either by a totally different way (maybe this is trivial if you look at it from some different perspective or something), or finish my incomplete proof below. Of course you would also answer my question if you can find a counterexample but I doubt you will be able to. Here is what I have so far: (Incomplete) proof: Fix a circle pairing f such that the point at infinity is in neither circle which is paired. In other words, fix a Möbius transformation f such that there exist 2 circles J_1, J_2 such that the point at infinity is in the exterior of both, and such that the exterior of J_2 is mapped to the interior of J_1, and the interior of J_2 is mapped to the exterior of J_1. Say f has coefficients a,b,c,d. We have that f maps the point at infinity to a/c, as is the case for all Möbius transformations. Denote the inverse of f as F, which clearly has coefficients $d,-b,-c,a$. We have that F maps the point at infinity to $-d/c$. This implies that f maps $-d/c$ to the point at infinity. Consider the line through a/c and $-d/c$, and choose some complex number H which lies on this line, between

a/c and $-d/c$ (so formally such that the distance from H to both a/c and $-d/c$ is strictly smaller than the distance between a/c and $-d/c$). Given that we already know that $inf->a/c, -d/c->inf$ and $H=/=a/c,-d/c$, we have that H is mapped to some complex number J (Side note: by a theorem above we have that all information about the circle pairing has to be contained in the fact that inf->a/c, $-d/c$->inf, H->J, so H and J would somehow have to capture information about circles around a/c and $-d/c$). Define the circle C_F through H with center $-d/c$. We have that C_F is mapped to some circle C_f through J (by one of the theorems above it is mapped to a line or circle, but because $-d/c$ is not on the circle it can only be mapped to a circle, and because $H->J$ it must be a circle through J; FYI a line is a circle through the point at infinity). If we can show that this image circle always has a/c as center we are done as by some theorem in topology it follows that then f is a circle pairing where the circles which are paired are C_F and C_f. Possible leads which might help with finishing the proof (from huge leads to less promising leads): Maybe we can argue using the inverse map F, which is also a circle pairing, hence it should behave similarly to f. As f maps C_F to some circle C_f through J we have that F maps C_f to C_F. Furthermore we have because F is also a circle pairing, that we can consider the circle C_g through J (confusing notation maybe) with as center a/c and say that it is mapped to some circle through H. Now we have to show that $C_g=C_f$. Maybe this reasoning is even better as it could imply something for f directly, but I'm not sure. Something related to symmetry. If it somehow follows that by symmetry there must be some other point on C_F which is mapped to the reflection of J in the line through a/c and $-d/c$, and another point on C_F is mapped to some other point on this line, then maybe that could help. Something related to the side note in my incomplete proof above. Maybe there is some shortcut by using this in combination with some other theorem I don't know about. It should be possible to argue that a/c must lie inside C_f by the fact that we are considering a circle pairing. I.e. use the fact that we know that at least some circles are paired, and because the point at infinity is in neither is is mapped to the interior of the other circle. Something related to the distance between H and the other intersection point of the line through a/c and $-d/c$ which is on C_F. This might give a clue on the diameter of the image circle. The line through a/c, $-d/c$ and H is mapped to a line through J and the image of a/c. For the image of a/c we know that it is mapped to some number W which has smaller distance to the attracting fixed point of f. The only line which can be preserved is the line through a/c and $-d/c$ (as the point at infinity lies on every line, is mapped to a/c and $-d/c$ is mapped to the point at infinity). If the attracting fixed point lies on the line through a/c and $-d/c$ then it is mapped to the line through J and that fixed point. Thanks in advance if you are willing to help :)

Difference between hypotenuse and larger leg in a Pythagorean triple

I've been number crunching irreducible Pythagorean triples and this pattern came up: the difference between the hypotenuse and the larger leg seems to always be n^2 or $2n^2$ for some integer n. Moreover, every integer of the form n^2 or $2n^2$ is the difference between hypotenuse and the larger leg for some irreducible Pythagorean triple. Is there a simple proof for that? There is a result listed on Wikipedia that looks kinda, sorta related: that the area of a Pythagorean triangle can not be the square or twice the square of a natural number. EDIT: Actually, the statements are correct only for odd n^2 (but also by any $2n^2$ as stated) as John Omielan demonstrated below.

Is it true that $\frac{a_1^2}{a_2}+\frac{a_2^2}{a_3}+\cdots+\frac{a_n^2}{a_1}\geq\sqrt{n(a_1^2+a_2^2+\cdots+a_n^2)}$ for positive real a_i?

This problem is my attempt to generalize an easier problem: Let $a_1,a_2,\dots,a_n$ be n positive real numbers. Prove or disprove that: $$\frac{a_1^2}{a_2} + \frac{a_2^2}{a_3} + \dots + \frac{a_n^2}{a_1} \geq \sqrt{n \left(a_1^2 + a_2^2 +\cdots+a_n^2 \right)}.$$ I was able to prove that the inequality holds for $n \leq 4$ using AM-GM and Cauchy-Schwarz but was stuck with $n \geq 5$ after much effort. I don't know if this generalization is true and if it really is then it'll be great if someone can show me some hints to prove it. Edit: To show my effort, I have included my solution to the case $n=4$ (for $n \leq 3$, a similar method can be applied) For $n=4$, we need to prove that: $$ \frac{a_1^2}{a_2} + \frac{a_2^2}{a_3} + \frac{a_3^2}{a_4} + \frac{a_4^2}{a_1} \geq \sqrt{4 \left(a_1^2 +a_2^2 + a_3^2 + a_4^2 \right)} $$ By using the Cauchy-Schwarz inequality, we have: $$ \left(a_1^2a_2 + a_2^2a_3 + a_3^2a_4 + a_4^2a_1 \right) \left(\frac{a_1^2}{a_2} + \frac{a_2^2}{a_3} + \frac{a_3^2}{a_4} + \frac{a_4^2}{a_1} \right) \geq \left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right)^2 $$ We also have: $$ a_1^2a_2 + a_2^2a_3 + a_3^2a_4 + a_4^2a_1 \leq \sqrt{\left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right) \left(a_1^2a_2^2 + a_2^2a_3^2 + a_3^2a_4^2 + a_4^2a_1^2 \right) }$$ Note that: $$ a_1^2a_2^2 + a_2^2a_3^2 + a_3^2a_4^2 + a_4^2a_1^2 = \left(a_1^2 + a_3^2 \right) \left(a_2^2 + a_4^2 \right) \leq \frac{\left(a_1^2+a_2^2+a_3^2+a_4^2 \right) ^2}{4} $$ $$\Longrightarrow \sqrt{\left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right) \left(a_1^2a_2^2 + a_2^2a_3^2 + a_3^2a_4^2 + a_4^2a_1^2 \right) } \leq \sqrt{\frac{\left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right)^3}{4}}$$ Therefore: $$ \frac{a_1^2}{a_2} + \frac{a_2^2}{a_3} + \frac{a_3^2}{a_4} + \frac{a_4^2}{a_1} \geq \frac{\left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right)^2}{\sqrt{\dfrac{\left(a_1^2 + a_2^2 + a_3^2 + a_4^2 \right)^3}{4}}} = \sqrt{4 \left(a_1^2 +a_2^2 + a_3^2 + a_4^2 \right)} \text{ (QED)} $$

Another 6 points circle associated with a triangle?

Consider a triangle ABC and a point D. For each of the triangles ABD, BCD, ACD construct the inscribed and circumscribed circles. Conjecture: For any triangle ABC there always exists a special location of D, so that six intersection points of these six circles are concyclic. Is this actually true or not? This construction gives us 12 intersection points , but we are only interested in the "orange" ones and not in the "green" ones. In other words, we only consider the first intersection points of the arches ADB,BDA,BDC,CDB,ADC,CDA with the inscribed circles. Geogebra dynamic sketch.

Conjecture about the density of primes

Conjecture For any sufficiently large integer kn , the sequence representing the number of primes in each block obtained by splitting kn into k equal blocks, is a strictly decreasing sequence, i.e: $$\pi\left(n\right)>\pi\left(2n\right)-\pi\left(n\right)>\pi\left(3n\right)-\pi\left(2n\right)\ldots>\pi\left(kn\right)-\pi\left(\left(k-1\right)n\right)$$ My approach For any given k, we need to prove that for all sufficiently large n, the last block contains less primes than the block before:
$$\underbrace{\pi\left(\left(k-1\right)n\right)-\pi\left(\left(k-2\right)n\right)}_{\text{before last}}>\underbrace{\pi\left(kn\right)-\pi\left(\left(k-1\right)n\right)}_{\text{last}}$$ Let $f(k,n)$ denote the difference between the prime count of before last and last block of kn:
$$f\left(k,n\right)= \left(\pi\left(\left(k-1\right)n\right)-\pi\left(\left(k-2\right)n\right)\right)-\left(\pi\left(kn\right)-\pi\left(\left(k-1\right)n\right)\right)$$
$$=2\pi\left(\left(k-1\right)n\right)-\pi\left(\left(k-2\right)n\right)-\pi\left(kn\right)$$ Therefore, an equivalent formulation of the conjecture is that $f(k,n)>0$ for any integers k,n with sufficiently large n. Does anybody have ideas or references on how to prove this? $$$$ Computation of $f(k,n)$ I made some computation that strongly suggests the conjecture is true, at least for small k: Failing case for small n Let's take the case $k=2$. We see that the conjecture fails for $n=1,2,4$ & 10: I computed $f(k,n)$ for $2 ≤ k ≤ 30$ with $1 ≤ n ≤ 10^{8}$, in order to find what appears to be the last failing case of each k , after which $f(k,n) >0$ for all n:

π found in Minesweeper - a new conjecture

Playing with Monte Carlo simulations over Minesweeper, I happened by chance to find π appearing in a pattern of the numbers relating to cells neighboring mines on $n\times n$ grids with n mines. My observations point to the following conjecture: We define S_n as the average sum of all numbers on a quadratic Minesweeper board with dimensions $n\times n$, and a number of mines equal to n. We define S_{n-1} as the average sum of all numbers on a quadratic Minesweeper board with dimensions $(n-1) \times (n-1)$, and a number of mines equal to $n-1$. Subtracting S_{n-1} from S_n yields approximately $7.85398 \approx 2.5\pi$. The full conjecture is given in a PDF here: Github link I, being a mere computer scientist, do not have enough insight into the topic, so I have discussed this with a professor of mathematics at my university. He thinks the edge effects are not that important, and suggests looking closer at the overlaps, further suggesting looking at the Minesweeper grid as a torus. What are your thoughts on this curious occurrence of π? Do you find any flaws in my conjecture?

Does the following lower bound improve on $I(q^k) + I(n^2) > 3 - \frac{q-2}{q(q-1)}$, where $q^k n^2$ is an odd perfect number? - Part II

Preamble: This question is an offshoot of these earlier posts: (post1), (post2). Let $N = q^k n^2$ be an odd perfect number with special prime q satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. Define the abundancy index $$I(x)=\frac{\sigma(x)}{x}$$ where $\sigma(x)$ is the classical sum of divisors of x. Since q is prime, we have the bounds $$\frac{q+1}{q} \leq I(q^k) < \frac{q}{q-1},$$ which implies, since N is perfect, that $$\frac{2(q-1)}{q} < I(n^2) = \frac{2}{I(q^k)} \leq \frac{2q}{q+1}.$$ By considering the negative product $$\bigg(I(q^k) - \frac{2(q-1)}{q}\bigg)\bigg(I(n^2) - \frac{2(q-1)}{q}\bigg) < 0,$$ since we obviously have $$\frac{q}{q-1} < \frac{2(q-1)}{q},$$ then after some routine algebraic manipulations, we arrive at the lower bound $$I(q^k) + I(n^2) > 3 - \frac{q-2}{q(q-1)} = \frac{3q^2 - 4q + 2}{q(q - 1)}.$$ In (post2), I derived the following inequality: $$2qn^2 - q\sigma(n^2) < 2n^2 - 1.$$ Using my method, I then get the bounds $$I(q^k) < \dfrac{q}{q-1} < \dfrac{2(q-1)}{q} + \dfrac{1}{qn^2} < I(n^2)$$ which implies that the product $$(I(q^k) - x)(I(n^2) - x) < 0$$ is negative, where $$x = \dfrac{2(q-1)}{q} + \dfrac{1}{qn^2}.$$ Upon some algebra, I get $$I(q^k) + I(n^2) > \dfrac{3q^2 - 4q + 2}{q(q - 1)} - \dfrac{q}{(q - 1)(2qn^2 - 2n^2 + 1)} + \dfrac{1}{qn^2}.$$ But $$- \dfrac{q}{(q - 1)(2qn^2 - 2n^2 + 1)} + \dfrac{1}{qn^2} = \dfrac{qn^2 (q - 4) + q + 2n^2 - 1}{qn^2 (q - 1)(2n^2 (q - 1) + 1)} > 0,$$ since q is a prime satisfying $q \equiv 1 \pmod 4$ implies that $q \geq 5$. So it does appear that the inequality $$I(q^k) + I(n^2) > \dfrac{3q^2 - 4q + 2}{q(q - 1)} - \dfrac{q}{(q - 1)(2qn^2 - 2n^2 + 1)} + \dfrac{1}{qn^2}$$ is unconditionally true, which would mean that the new lower bound for $I(q^k) + I(n^2)$ improves on the old. Note that we were able to prove this analytically. And lastly: Based on this answer to a closely related question, since we appear to have obtained an improved lower bound for $I(q^k) + I(n^2)$, can we then say that there is indeed an integer a such that $k \leq a$?

Does $\sigma(n^2)/q \mid q^k n^2$ imply $\sigma(n^2)/q \mid n^2$, if $q^k n^2$ is an odd perfect number with special prime q?

Denote the classical sum of divisors of the positive integer x by $\sigma(x)=\sigma_1(x)$. Denote the abundancy index of x as $I(x)=\sigma(x)/x$. I discovered an interesting identity involving divisors of odd perfect numbers given in the Eulerian form $N = q^k n^2$ today (July 13, 2021). (Recall that an odd perfect number $N = q^k n^2$ is said to be given in Eulerian form if q is the special prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$.) The identity is: Proposition: If $N = q^k n^2$ is an odd perfect number with special prime q, then $$N\cdot\Bigg(I(n^2) - \frac{2(q - 1)}{q}\Bigg) = \frac{\sigma(n^2)}{q}.$$ Proof: Our starting point is the following blog post, where it is proved that $$\gcd(n^2, \sigma(n^2)) = 2(1 - q)n^2 + q\sigma(n^2).$$ However, note that we have $$\frac{\sigma(n^2)}{q^k} = \gcd(n^2, \sigma(n^2)).$$ These equations are equivalent to $$2(1 - q)n^2 + q\sigma(n^2) = \frac{\sigma(n^2)}{q^k}.$$ Factoring out qn^2 on the LHS, we obtain $$qn^2 \Bigg(I(n^2) - \frac{2(q - 1)}{q}\Bigg) = \frac{\sigma(n^2)}{q^k}.$$ Multiplying both sides of the last equation by q^{k-1}, we get $$N\cdot\Bigg(I(n^2) - \frac{2(q - 1)}{q}\Bigg) = \frac{\sigma(n^2)}{q}.$$ (Note that the RHS of the last equation is an odd integer.) This concludes our proof. QED. In particular, we have $$\frac{N}{\sigma(n^2)/q} = \frac{1}{\Bigg(I(n^2) - \frac{2(q - 1)}{q}\Bigg)}.$$ But we also know from the following MSE post that $$I(n^2) - \frac{2(q - 1)}{q} = \frac{2(q - 1)}{q\bigg(q^{k+1} - 1\bigg)}.$$ This means that we obtain $$\frac{1}{\Bigg(I(n^2) - \frac{2(q - 1)}{q}\Bigg)} = \frac{q\bigg(q^{k+1} - 1\bigg)}{2(q - 1)} = \frac{q\sigma(q^k)}{2}.$$ But $\sigma(q^k) \equiv k + 1 \pmod 4$, since $q \equiv 1 \pmod 4$, and since $k \equiv 1 \pmod 4$, then $$\sigma(q^k) \equiv k + 1 \equiv 2 \pmod 4.$$ This finding implies that $\sigma(n^2)/q$ divides $N = q^k n^2$. Here is my: QUESTION: Does $\sigma(n^2)/q \mid q^k n^2$ imply that $\sigma(n^2)/q \mid n^2$? If not, under what condition(s) does this implication hold? Note that a proof for $\sigma(n^2)/q \mid n^2$ would imply the Descartes-Frenicle-Sorli Conjecture that $k=1$.

Conjecture about the Carmichael function

Let $\ \lambda(n)\ $ denote the Carmichael-function and define $\ n(e)\ $ to be the number of solutions of $\ \lambda(m)=e\ $. For $\ e\ge 3\ $, we have $\ 4\mid n(e)\ $ I chose "$\ e\ $" because we can concentrate on then even numbers because clearly for odd $\ e\ge 3\ $, there is no solution of $\ \lambda(m)=e\ $, hence $\ n(e)=0\ $ in this case. For $\ e=2\ $, we have $\ 6\ $ solutions , the divisors of $\ 24\ $ except $\ 1\ $ and $\ 2\ $. But for $\ 4\le e\le 3\ 000\ $, we have $\ 4\mid n(e)\ $ as the conjecture states ($\ n(e)=0\ $ can occur as well). Can we prove this conjecture ? The possible prime factors $\ p\ $ of $\ m\ $ have the property $\ p-1\mid e\ $ and $\ p^k\mid m \implies p^{k-1}\cdot (p-1)\mid e\ $. This allows to find all the solutions. With this algorithm (there might be better ones , but I am not aware of anything better), I checked $\ n(e)\ $ upto $\ e=3\ 000\ $ for divisibility by $\ 4\ $. The conjecture would imply a solution to a problem similar to this open conjecture , namely with $\ \lambda(n)\ $ instead of $\ \varphi(n)\ $.

Conjecture about divergent periodic summations of odd functions

$$f(x)=\lim_{m\to\infty}\frac{\sum_{n=-m}^m(x-n)^{1/3}}{\sum_{n=-m}^m(1-n)^{1/3}}\stackrel{?}{=}x$$ I had a 'proof' but I made the simple mistake of assuming 2 limits could be swapped, so I only really proved that $f(x)=x$ for $x\in[-1,0,1]$, which is pretty trivial. Here's the 'proof' that I had. This was a first draft so it may be confusing to read. The $(\text{stuff})^{1/3}$ in the numerator and denominator is really just $g(\text{stuff})$. Where g just needs to be any odd function and relatively smooth and have a few other properties that I don't remember.

Why is $\ 100\ $ so special in this context?

Let $\ \lambda(k)\ $ be the Carmichael function and denote $\ N(n)\ $ to be the number of solutions of $\ \lambda(k)=n\ $ Can we prove that $\ N(n)=n\ $ only holds for $\ n=100\ $ (besides the uninteresting case $\ n=0\ $) ? Odd numbers can be ruled out since $\ N(1)=2\ $ and $\ N(u)=0\ $ for every odd $\ u\ge 3\ $. A number $\ n\ $ with $\ n\equiv 2\mod 4\ $ cannot be a solution because of $\ N(2)=6\ $ and for $\ n\ge 6\ $, we can easily show that $\ N(n)\ $ must be divisible by $\ 4\ $. Hence , we can concentrate on the multiples of $\ 4\ $. Maybe someone finds additional restrictions. Using recursive computation of $\ N(n)\ $, I verified the conjecture upto $\ n=10^7\ $. Does anyone have an idea why $\ 100\ $ is so special here ?

Is it true that $\frac{D(n^2)}{s(q^k)} > \frac{\sigma(q^k)}{2}$, if $q^k n^2$ is an odd perfect number given in Eulerian form?

Preamble: This post is an attempt to resolve the problem in this earlier question. Let $\sigma(x)$ denote the sum of divisors of the positive integer x. A number M is said to be perfect if $\sigma(M)=2M$. For example, 6 and 28 are perfect since $$\sigma(6) = 1 + 2 + 3 + 6 = 2\cdot{6}$$ and $$\sigma(28) = 1 + 2 + 4 + 7 + 14 + 28 = 2\cdot{28}.$$ It is currently unknown if there are infinitely many even perfect numbers. It is also an open problem whether any odd perfect numbers exist. It is widely believed that there are no odd perfect numbers. Euler proved that an odd perfect number N, if one exists, must necessarily have the so-called Eulerian form $$N = q^k n^2$$ where q is the special/Euler prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. UNDERLYING PROBLEM Here is the problem that I am considering: Can the odd perfect number N be of the form

$$\frac{q^k \sigma(q^k)}{2}\cdot{n}?$$ CONTEXT Slowak (1999) proved that the odd perfect number N must be of the form $$\frac{q^k \sigma(q^k)}{2}\cdot{d},$$ where $d > 1$. Dris (2017) showed further that d must have the form $$\frac{D(n^2)}{s(q^k)}=\gcd(n^2,\sigma(n^2))=\frac{\sigma(n^2)}{q^k}=\frac{n^2}{\sigma(q^k)/2},$$ where $D(x)=2x-\sigma(x)$ is the deficiency of x, and $s(x)=\sigma(x)-x$ is the aliquot sum of x. MY ATTEMPT Dris and San Diego (Theorem 5.6, page 22) proved that $$D(n^2) > \frac{q+1}{2}.$$ Since it is not true that $$\frac{D(n^2)}{s(q^k)} \leq D(n^2) \leq \frac{q+1}{2} \leq \frac{\sigma(q^k)}{2},$$ can we then say that $$\frac{D(n^2)}{s(q^k)} > \frac{\sigma(q^k)}{2}?$$ If so, this would imply that $$\frac{\sigma(n^2)}{q^k} = \frac{n^2}{\sigma(q^k)/2} > \frac{\sigma(q^k)}{2}$$ which would mean that $$n > \frac{\sigma(q^k)}{2}.$$ In particular, we have that $$\frac{2n}{\sigma(q^k)} > 1$$ which implies that $$\frac{\sigma(n^2)}{q^k} = \frac{2n^2}{\sigma(q^k)} > n > \frac{\sigma(q^k)}{2}.$$ This appears to prove that $\sigma(n^2)/q^k \neq n$. Here is my: QUESTION: Does this proof hold water? If not, how can it be mended so as to produce a valid proof?

Is this proof regarding the nonexistence of odd perfect numbers correct?

Preamble: This post is an offshoot of this earlier question, which was not so well-received in MathOverflow. Let $\sigma(x)=\sigma_1(x)$ denote the classical sum of divisors of the positive integer x. Denote the abundancy index of x by $I(x)=\sigma(x)/x$. If m is odd and $\sigma(m)=2m$, then m is called an odd perfect number. Euler proved that a hypothetical odd perfect number must necessarily have the form $$m = q^k n^2$$ where q is the special/Euler prime satisfying $q \equiv k \equiv 1 \pmod 4$ and $\gcd(q,n)=1$. As proved in MO, we have the following equation: $$I(n^2) - \frac{2(q - 1)}{q} = \frac{1}{q^{k+1}}\cdot{I(n^2)},$$ whereupon, starting from the lower bound $$I(n^2) > \frac{2(q - 1)}{q}$$ we get the recursive estimates $$I(n^2) > \frac{2(q - 1)}{q} + \frac{1}{q^{k+1}}\cdot\frac{2(q - 1)}{q}$$ $$I(n^2) > \frac{2(q - 1)}{q} + \frac{1}{q^{k+1}}\bigg(\frac{2(q - 1)}{q} + \frac{1}{q^{k+1}}\cdot\frac{2(q - 1)}{q}\bigg)$$ $$= \frac{2(q - 1)}{q}\cdot\Bigg(1 + \frac{1}{q^{k+1}} + \bigg(\frac{1}{q^{k+1}}\bigg)^2\Bigg)$$ $$I(n^2) > \frac{2(q - 1)}{q} + \frac{1}{q^{k+1}}\Bigg(\frac{2(q - 1)}{q}\cdot\Bigg(1 + \frac{1}{q^{k+1}} + \bigg(\frac{1}{q^{k+1}}\bigg)^2\Bigg)\Bigg)$$ $$= \frac{2(q - 1)}{q}\cdot\Bigg(1 + \frac{1}{q^{k+1}} + \bigg(\frac{1}{q^{k+1}}\bigg)^2 + \bigg(\frac{1}{q^{k+1}}\bigg)^3\Bigg)$$ $$\ldots$$ $$\ldots$$ $$\ldots$$ Repeating the process ad infinitum, we get: $$I(n^2) > \frac{2(q - 1)}{q}\cdot\Bigg(\sum_{i=0}^{\infty}{\bigg(\frac{1}{q^{k+1}}\bigg)^i}\Bigg).$$ But $$\sum_{i=0}^{\infty}{\bigg(\frac{1}{q^{k+1}}\bigg)^i}$$ is an infinite geometric series, with sum $$\frac{a_0}{1 - r}$$ where the first term $a_0 = 1$ and the common ratio $$r = \frac{1}{q^{k+1}}.$$ Hence, we obtain $$\sum_{i=0}^{\infty}{\bigg(\frac{1}{q^{k+1}}\bigg)^i} = \frac{1}{1 - \frac{1}{q^{k+1}}},$$ from which we finally get $$I(n^2) > \frac{2(q - 1)}{q}\cdot\frac{q^{k+1}}{q^{k+1} - 1}.$$ But we can simplify the RHS of the last inequality as follows: $$\frac{2(q - 1)}{q}\cdot\frac{q^{k+1}}{q^{k+1} - 1} = \frac{2q^k (q - 1)}{q^{k+1} - 1} = \frac{2q^k}{\sigma(q^k)} = \frac{2}{I(q^k)} = I(n^2).$$ We have therefore finally arrived at the contradiction $$I(n^2) > I(n^2).$$ We therefore conclude that there cannot be any odd perfect numbers. Here is my: QUESTION: Does this proof hold water? If it does not, where is the error in the argument, and can it be mended so as to produce a valid proof?

New method for constructing six-point circles?

I would like to present a circle associated with a triangle that can be constructed as follows: Let A' be the first intersection point of the bisector of angle A with the inscribed circle of the triangle ABC and define B' and C' cyclically. I is the incenter of the triangle ABC. Then circumcircles of the triangles A'B'I, B'C'I, A'C'I intersect the sides of the original triangle at six points, that are always concyclic: Geogebra dynamic sketch I wonder what triangle centres (if any) might be lying on this "red circle" and what is known about it? Point Z (the center of the "red circle" that is passing through six points) is not included into the Clark Kimberling's Encyclopedia... Mathworld.wolfram.com doesn't mention it as well. P.S. The same construction can be also applied to other remarkable circles: Geogebra dynamic sketch for the Taylor point/circle. Geogebra dynamic sketch for a Cevian circle of the Symmedian point. <slightly different construction principle was applied here, but overall it is the same idea. X(6) is not the center of the Symmedian circle> Geogebra dynamic sketch for the nine point circle So perhaps this principle holds true for all central circles and there might be some sort of a generalisation?

Conjecture:$\int_{0}^{\infty} \frac{\sin^3(x)\sin(3\pi x)}{x^4} J_0(x)^2\text{d}x \overset{?}{=} \frac{\pi}{2}$

I found $$\int_{0}^{\infty} \frac{\sin^3(x)\sin(3\pi x)}{x^4} J_0(x)^2\text{d}x=1.570796... \overset{?}{=} \frac{\pi}{2}$$ Where $J_0(x)$ is the 0th Bessel functions of the first kind. I try to use the following identity, $$\int_{-\infty}^{\infty} J_0(x)e^{-i\omega x}\text{d}x =\frac{1}{\sqrt{1-\omega^2} }$$ And $$\int_{-\infty}^{\infty} f(x)g(x)e^{i\omega x}\text{d}x =\frac{1}{2\pi} \int_{-\infty}^{\infty} F(x)G(\omega-x)\text{d}x$$ Where $F(x)=\int_{-\infty}^{\infty} f(t)e^{-itx}\text{d}t, G(x)=\int_{-\infty}^{\infty} g(t)e^{-itx}\text{d}t$. But the integral $\int_{-\infty}^{\infty} J_0(x)^2e^{i\omega x}\text{d}x$ involves $K(k)$(Complete elliptic integral of the first kind).So it's not a good way to prove it. Now I don't have any idea to prove it. Are there any hints? Or what techniques should I use?

Conjecture: there is only one configuration of d lines in n dimensional space where any pair have same angle and d is the max possible.
